Both arterial and venous blood sugars were determined simultaneously in the eight patients listed in Table III. The tolerance is much diminished following a high fat diet, but is improved following a high carbohydrate diet. The effect of insulin is the same as in the normal individuals and points to a definite diminution in tolerance. Comparison of the arterial and venous blood sugars reveals a definite flattening of both the arterial and venous curves following a high carbohydrate diet, with a greater effect on the arterial curve. In four of the eight patients there occurred an increase in the arteriovenous difference following the use of a high fat diet.

Chart I was obtained by plotting the average values of both arterial and venous blood sugars so that an idea of the effect of diet and insulin might be ob-

tained at a glance. The flattening of both arterial and venous curves in the normal individual following the high carbohydrate diet is striking. Following insulin, the curve resembles that obtained by a high fat diet. It will be noted that the arthritic person tends to have a higher blood sugar following a carbohydrate test meal than does the normal individual; nevertheless, the response to a high carbohydrate diet, as well as to insulin, is similar to the effect produced in the normal individual. Following a high carbohydrate diet, the arterial curve of the arthritic person approaches that of the normal, indicating an improved utilization of sugar by the liver.

DISCUSSION

The result of our work demonstrates that a diminished tolerance for carbohydrates exists in rheumatoid arthritis, as was reported by Pemberton and

Chart 1.

others. Following a two weeks' course of insulin, these patients have a decreased tolerance to glucose, as well as a diminution in arteriovenous difference similar to those exhibited by our normal controls. This only adds to common knowledge that insulin is diabetogenic when given to a person without diabetes over a long period of time. Various explanations have been offered to account for the diminished tolerance to glucose: (a) disturbance of pancreatic function, (b) diminished circulation causing a slowing in the removal of sugar from the blood, and (c) hepatic dysfunction. From the evidence submitted, it would seem that the most important role is played by the liver. This is shown by (1) the improvement following the high carbohydrate diet, (2) a decrease in arterial blood sugar levels following a carbohydrate test meal, and (3) no loss in glycogenic function of the muscles. The evidence presented does not, we believe, aid materially in the determination of the etiology of this disease. Chronic infection may produce metabolic changes similar to those seen in these patients. But other conditions, such as avitaminosis and endocrine disturbances, may likewise produce a similar picture.

Although insulin seemed to decrease the tolerance to glucose, an improvement in appetite of all patients was noted. No definite gain in weight and no effect on the course of the arthritis were demonstrated. None of the patients studied complained of an increase in pain while on the high carbohydrate diet. There was no evidence of increased pathologic activity within the joint during this regime. The opposite was true, however, in that the patients experienced a sense of well-being and frequently asked that they be kept on a high carbohydrate diet.

SUMMARY AND CONCLUSIONS

1. The effects of a high fat diet, a high carbohydrate diet, and a high carbohydrate diet with insulin on the tolerance to dextrose was observed in three normal persons and in eleven patients with rheumatoid arthritis.

2. Simultaneous arterial and venous true sugar tolerance curves were obtained on three normal persons and on eight with arthritis. Venous curves alone were run on three persons with arthritis.

3. The tolerance to glucose was improved in all persons with arthritis and in the normal person after a high carbohydrate diet.

4. Insulin decreased the tolerance to glucose in all patients studied.

5. The evidence submitted suggests that the decreased tolerance to glucose in the individual with arthritis is due to decreased glycogenic liver function rather than to pancreatic dysfunction or circulatory stasis.

6. There was no evidence of increased pain or increased disability in the person with arthritis while on the high carbohydrate regime.

VARIATIONS IN THE COMPOSITION OF GASTRIC JUICE*

INFLUENCE OF PROTEIN ON THE ACIDITY AND PEPSIN

M. J. MATZNER, M.D., C. WINDWER, M.D., O. GAWRON, B.S., M.A., AND
A. E. SOBEL, CH.E., PH.D., BROOKLYN, N. Y.

THE purpose of the present series of investigations is to study systematically the effect of proteins, carbohydrates, and fats on the acidity and pepsin activity (at constant pH) of the gastric secretions.

The hitherto available data on the *simultaneous* study of the pepsin activity, pH, and free and total acidity are scarce. This is especially true for the pepsin method of Anson and Mirsky¹ and the hydrogen-ion determination by the more reliable potentiometric methods. There are no data available for studying the influence of the three main food classifications into which diets may be divided in conjunction with the sensitive double histamine test proposed by Rivers, Osterberg, and Vanzant.²

The report presented here gives the results of the protein study. The protein used was gelatin. It was selected because of its purity, availability, ease of administration, and solubility in the gastric contents.

METHODS

All observations were made on patients who gave clinical and x-ray evidence of peptic ulcer.

The procedure for carrying out the test meal was as follows: The patient presented himself in the fasting state. A Rehffuss tube was introduced into the stomach, and the fasting contents were withdrawn. Five-tenths milligram of histamine hydrochloride was then injected hypodermically, and immediately afterwards 120 c.c. of tap water were given orally. Five to ten cubic centimeter samples of gastric juice were then aspirated at fifteen-minute intervals for one hour. At the end of the hour the entire stomach contents were removed and 0.5 mg. of histamine hydrochloride was again injected. Immediately afterwards 120 c.c. of tap water were given orally. When the effect of the protein was to be determined, a suspension of 15 Gm. of U.S.P. gelatin in 120 c.c. of tap water was given. Five to ten cubic centimeter samples of gastric juice were then aspirated at successive fifteen-minute intervals for one hour. The patient was told to expectorate his saliva throughout the test.

After collection each sample was placed in the refrigerator. The samples in most instances were free from mucus and did not require filtering. The pH

*From the Department of Gastro-enterology and the Pediatric Research Laboratory, the Jewish Hospital of Brooklyn.

Received for publication, December 18, 1939.

and the free and total acidity were determined within two hours after collection of the last sample. Pepsin determinations were done the following morning on a portion of the gastric juice diluted with 0.1 normal hydrochloric acid and kept in the refrigerator overnight. Pepsin values were found to be constant under these conditions.

The pH determinations were made with the Beckmann glass electrode. Free and total acidities were determined in the usual manner by titration. Values are expressed in terms of milliequivalents (meq.) per 1,000 c.c. These are numerically equivalent to what is commonly referred to as free and total acidity. The pepsin content was determined by the method of Anson and Mirsky¹ following the procedure outlined by Mullins and Flood.³ Pepsin values are expressed as milligrams of pepsin (1:4,000) per cubic centimeter of gastric juice, as suggested by Helmer, Fouts, and Zerfas,⁴ and Mullins and Flood.³ In carrying out the pepsin estimations, all dilutions were made with 0.1 normal hydrochloric acid.

Influence of Protein on the pH, Pepsin, and Free and Total Acidity of Gastric Juice During a Modified Double Histamine Test.—In testing the effect of the protein on the gastric secretions in vivo, a group of 16 patients with peptic ulcer were given the double histamine test without the protein (water group) after the first hour, and a separate group of 19 patients with peptic ulcer were given the double histamine test with the protein after the first hour (protein group).

Table I presents the mean values of pH, pepsin, and free and total acidity for these two groups. The significance of the difference between the mean values were evaluated by the statistical methods of Fisher⁵ as applied to small samples. P represents the frequency with which the difference between two means may be due to chance alone. When P is 0.05 or less, the difference between the means is considered significant.

It can be seen in Table I that during the first hour no statistically significant differences exist between the mean pH, pepsin, and free and total acidity values for the two groups. During the second hour, when one group received protein in addition to water, statistically significant differences can be noted between the mean pH, pepsin, and free acidity values for the first forty-five minutes. The total acidity values show no statistically significant changes during this period.

Thus protein in the form of gelatin when introduced into the stomach raises the pH markedly for at least thirty minutes and noticeably for forty-five minutes, markedly lowers pepsin and free acidity of the stomach for thirty minutes and noticeably for forty-five minutes, but has no effect on the total acid concentration.

Influence of the Protein on pH, Pepsin, and Free and Total Acidity in Vitro.—Since the concentration of the various constituents of the gastric juice depends on both chemical and secretory mechanisms, in vitro experiments testing the purely chemical effect of protein in the form of gelatin on acidity and pepsin were also carried out. The results are presented in Table II.

It can be seen in Table II that the protein (gelatin) markedly reduces the free acidity and causes a definite increase in the pH and a slight increase in the total acidity values. These findings are due to the acid-combining properties of

the protein on the acid side of the isoelectric point and to the base-combining power on the alkaline side of the isoelectric point. The presence of the protein has no effect on the pepsin values, as determined by the method of Anson and Mirsky.¹

The possibility that pepsin may be destroyed when the pH of a pepsin solution is raised by addition of the protein and incubated at 37° C. for an hour was then investigated. It was found that raising the pH from 1.3 to 4.0 by the addition of the protein and thereafter incubating at 37° C. has no effect on the peptic activity, as determined by the Anson-Mirsky method.

TABLE II

INFLUENCE OF PROTEIN (GELATIN) ON THE ACIDITY AND PEPSIN IN VITRO

150	0	0	70	120	3.5	4.4	4.9	

The possibility that the pepsin digestion products of the protein would reduce peptic activity was also investigated. It was found that pepsin activity remained constant when the protein is digested at a pH of 3.0 for one hour at 37° C. This is in harmony with Northrop's experiments⁶ which show that the digestion of gelatin by pepsin takes place very slowly and then not to any great extent.

DISCUSSION

From the results obtained, it is to be seen that protein in the form of gelatin significantly reduces the hydrogen-ion concentration and pepsin, but not the total acid concentration of the gastric juice. This reduction of the hydrogen-ion concentration in the stomach is similar to the in vitro reduction of acid by the protein. The amount of reduction depends upon the quantity of acid present and the amount of protein added, as shown in Table II.

The effect of the protein on total acidity in vivo is also in harmony with the in vitro findings where (as seen in Table II) the presence of gelatin in small concentrations causes only slight variations in the total acidity. In the in vivo experiments gelatin was given in a concentration of 12 per cent. This concentration is quickly reduced by the addition of fluid from the gastric secretions, so that the concentration present in the stomach is considerably less than 12 per cent. In terms of total acidity this would mean an increase by only a few milliequivalents per 1,000 c.c. In line with this, no significant differences in the total acid was noted between the protein and control groups.

From the in vitro experiments performed, the mechanism by which the pepsin concentration is lowered in the stomach, in the presence of protein in the

form of gelatin, cannot be ascribed to any competitive retardation of peptic activity by the protein or to the destruction of pepsin when the pH is raised by the protein or to the inhibition of peptic activity by the digestion products of the protein. The factors that are possibly responsible for the lowering of the pepsin content of the gastric juice following the administration of the protein may be either a lowered volume rate of secretion of pepsin or a retardation in the rate of conversion of the pepsin precursor, pepsinogen, to pepsin.

SUMMARY

1. The influence of protein (in the form of gelatin) on the acidity and pepsin of the gastric juice of patients suffering from peptic ulcer was investigated by means of a modified double histamine test.

2. The hydrogen-ion concentration, the free acid, and the pepsin were reduced. The total titrable acidity was not appreciably influenced.

3. On the basis of in vitro experiments the reduction of the hydrogen-ion concentration and free acidity of the gastric juice may be ascribed to the acid-combining power of the protein.

4. The reduction of the pepsin content of the stomach, on the basis of in vitro experiments, cannot be ascribed to the protein per se, but possibly to a reduced secretion of pepsin or a retarded conversion of pepsinogen to pepsin.

We are indebted to Dr. C. A. Flood, of the Columbia College of Physicians and Surgeons, for his helpful suggestions regarding the technique of pepsin estimations.

A CRITICAL SURVEY OF A PHENOLPHTHALEIN TEST FOR GASTROINTESTINAL LESIONS*

NATHANIEL E. REICH, M.D., BROOKLYN, N. Y.

IN VIEW of the need for a simple test to determine the presence of gastrointestinal lesions quickly and accurately, Woldman¹ devised a procedure based upon the urinary excretion of peroral phenolphthalein when a break exists in the mucosa of the digestive tract.

The patient in a fasting state is given 0.1 Gm. (1.5 gr.) of white phenolphthalein dissolved in 10 c.c. of 95 per cent alcohol, diluted with 20 c.c. of water. Specimens of urine are obtained two and four hours later and tested immediately for the presence of free phenolphthalein by the addition of a 10 per cent solution of sodium hydroxide. Woldman assumes that the appearance of a pink color indicates that free phenolphthalein has actually passed through a break in the continuity of the gastrointestinal mucous membrane into the blood and is finally excreted in the urine. Normally, it is excreted as conjugate phenolphthalein which fails to give this specific reaction. Prolongation of the test beyond four hours did not aid its diagnostic efficiency. Occasionally, the urinary pigments in very dark or highly colored urine presented a problem because of the masking of the faint pink color reaction of the indicator. Greene² suggested an improvement on the test by the addition of suspensions of the hydroxides of zinc, calcium, or barium to remove the pigments in the urine and at the same time produce the necessary alkalization. Comparative tests run concomitantly on such urines showed a more visible pink with these suspensions. However, it required from two to three times the amount of these alkalis to get the necessary alkalization. Therefore, whenever the test is employed, it is suggested that one of these alkalis be made available for highly colored urines.

Among the advantages of the test are enumerated its usefulness in cases where the roentgenographic diagnosis is doubtful or impossible to perform, in ruling out organic lesions of the gastrointestinal tract in diseases which may have symptoms referable to the digestive system, in differentiating functional from organic disease, and its simplicity, rapidity, and inexpensiveness. Woldman also reports an amazing accuracy for a laboratory test of its kind, with a possible error of less than 3 per cent for both positive and negative findings.

The test proved to have several serious disadvantages in our hands. The percentage of error in our series of cases is much greater than that reported, and, therefore, the test loses much of its specificity. In a series of 46 persons with proved gastrointestinal lesions, 22 failed to give a positive reaction, resulting in

*From the Kings County Hospital, service of Dr. C. H. Greene, and the Long Island College of Medicine Division, Dr. J. Hamilton Crawford, director.

Received for publication, December 29, 1939.

48 per cent error (Table I). A group of 105 nongastrointestinal control patients gave 25 false positive reactions, resulting in 24 per cent error (Table II). Upon repetition of the test on individuals with false positive reactions, practically the same results were obtained. The total error for both positive and negative findings was 38 per cent. These findings closely approximate the fairly uniform results obtained by other investigators (Table III).

Diabetes	1	0	1
Total	105	26	79

In view of the fact that the tests were performed exactly as outlined by Woldman, guarding against contaminations, and testing specimens immediately following their collection, so that free phenolphthalein could not possibly be formed from the conjugated compound on standing, causes were investigated to explain these wide discrepancies. Especially was an explanation sought for the presence of the many false positive reactions. Notkin, Kirsch, and Albert⁷ believe that this is due to the fact that certain cathartics (phenolphthalein, rhubarb, senna, and cascara) impart a brown color to the urine which changes to red on the addition of alkalis. Furthermore, uroscoscin and uroerythrin produce a similar color in an alkaline medium.

*Experimentally induced ulcers in dogs.

In an early exhaustive study Fleig⁴ proved that phenolphthalein is a stable compound which does not break down in the gastrointestinal tract into phenol and phthalic acid, and when given by mouth in larger doses, passes into the urine in its free state which may be discovered by the addition of alkali. Von Vamossy,⁵ who discovered the cathartic quality of phenolphthalein in 1902, found that more than 85 per cent of ingested phenolphthalein is eliminated in the feces of the dog and that a minimal quantity of free phenolphthalein is recovered from the urine, the remainder appearing as conjugated phenolphthalein.

Fantus and Dyniewicz⁶ indicated that after small medicinal doses free phenolphthalein is usually absent from the urine, but that the larger the dose, the more frequently does free phenolphthalein appear in the urine. The same authors,⁷ in more extensive studies on the elimination of phenolphthalein, demonstrated that three out of seven students receiving approximately the same dose (0.12 Gm.) as that used in the test, eliminated the following percentages of free phenolphthalein of the total dose: 0.1, 0.37, 1.06, respectively. Again, these authors¹⁷ recovered free phenolphthalein in 8.5 per cent of the urines of medical students and in 21.5 per cent of the urines of the patients at the Cook County Hospital without gastrointestinal lesions. Since free phenolphthalein shows its presence as a pink color in alkaline solutions in dilutions as high as 1:12,000,000 (0.1 Gm. to 120 liters),⁸ even the excretion of traces, which most investigators agree occurs, can give a positive test in normal persons, or in those without demonstrable organic gastrointestinal lesions. The occurrence of these traces of the free drug in the urine is the most important cause for its failure as a specific test in a large number of negative controls. Fantus and Dyniewicz⁶ reverse an earlier conception by concluding that the smaller the dose the larger the relative percentage of free phenolphthalein appearing, probably because the lesser amount of catharsis permits increased absorption. This may account for its urinary presence even with the smaller dosages.

More recently, Steigmann and Dyniewicz⁹ believe that there is a certain minimum of conjugated phenolphthalein below which no free phenolphthalein appears in the urine, and this amount is 5 mg. per 100 c.c. Therefore, in corroborating previous investigations,²³ the amount of conjugated phenolphthalein governs the absence or presence of free phenolphthalein. Hence, any condition which will promote an increased formation or circulation in the blood of the conjugated form will lead to the appearance of the free form in the urine. This also contradicts Woldman's assumption that free phenolphthalein depends entirely upon the presence of an ulcerative lesion. While increased intestinal absorption may play a role, the appearance of the free form depends so greatly upon the amount of the conjugated form that it is wrong, in their opinion, to attribute any special diagnostic importance to free phenolphthalein in the urine.

Patients with jaundice show practically 100 per cent free phenolphthalein present and would therefore appear to present a contraindication^{9, 10} to the test, since conjugation and excretion in the bile of the phenolphthalein do not occur in a diseased liver and it is consequently excreted in the urine in the free form.

All observers agree that cardiovascular-renal disease and the blood dyscrasias give a high percentage of positive results, probably due to greater mucosal permeability. According to Steigmann and Dyniewicz,⁹ in these cases the free phenolphthalein appears when the conjugated form is in a concentration lower than 5 mg. per cent.

It was more difficult to explain the presence of negative tests in patients with gastrointestinal lesions in which a positive test was expected. All persons tested had acute gastrointestinal complaints and all diagnoses were corroborated by laboratory and roentgenologic findings. The patients with gastrointestinal disturbances, all taken from the acute wards, suffered from peptic ulcer, gastric and colonic malignancies, ulcerative colitis, amoebic dysentery, typhoid, acute gastroenteritis, diverticulitis of the colon, intestinal tuberculosis, and hematemesis. It is possible that some of the carcinomas were not ulcerated and allowed no avenue of absorption, or that the other ulcerative lesions developed some protective antiabsorptive process. Rowland¹⁰ suggests that this is due to retained food or an adherent exudate on the ulcerations. Kremer, Shore, and Wiesel¹³ are of a similar opinion. It may be that the dosage is the important factor, since 1.5 grains of phenolphthalein may give a negative test repeatedly, while 4 grains gives a positive test regularly in the normal person.

Other objections are those associated with the gastrointestinal disturbances which the test is capable of producing (Table IV). The routine use of the alcoholic solvent (10 c.c. of 95 per cent alcohol) in cases with acute involvement of the upper tract, notably hematemesis and gastric ulcer, is considered inadvisable. It has a tendency to produce temporary gastric distress and enhances the possibility of further bleeding. Clark¹¹ commented on the fact that alcohol taken upon an empty stomach in concentrations above 10 per cent produces gastric irritation and causes an initial secretion of gastric juice which is followed by an inhibition persisting for as long as twenty-four hours. The resulting increased gastric secretion is, of course, especially inadvisable in peptic ulcer. Other vehicles for the phenolphthalein were found by Fantus and

Dyniewicz,⁶ after a comprehensive study of solvents, to be unsuitable because of insolubility or marked irritability, making the use of an alcoholic solvent imperative.

TABLE IV
TOXIC EFFECTS OF THE PHENOLPHTHALEIN TEST

	CASES	PERCENTAGE
Nausea	41	30.0
Vomiting	9	6.5
Abdominal cramps	16	11.7
Diarrhea	11	8.0
Laxative effect	72	47.0
Anorexia	20	13.2
Skin	0	0
Pyrexia	5	3.6
Kidney manifestations	0	0

Many of our patients complained of nausea and a few vomited; the vomiting may have been due in part to a superimposed psychic factor. Indigestion of subsequent food or anorexia was a source of annoyance for another group of patients. The most serious digestive derangement, however, was diarrhea. Although Woldman states that a small dose of 0.1 Gm. is without laxative effect, Fantus and Dyniewicz⁷ record these effects in practically all of their normal individuals, even with approximately half as large a dose as that employed in the test (0.06 Gm.). Some degree of laxation occurred in almost half our patients, while others⁹ report it in as high as 80 per cent of their patients. Abramowitz⁸ has indicated that the laxative action of phenolphthalein is further enhanced when the drug is ingested in an alcoholic solution. Gunn¹² pointed out that after its solution by bile and alkali in the intestine, phenolphthalein produces purgation by mild irritation of the small bowel and especially the large bowel. Some of it may be absorbed and re-excreted into the intestine so that its purgative action may last for a few days. Such was the case in our group of patients, especially those with typhoid, ulcerative colitis, or gastric malignancy. It was even more pronounced where diarrhea existed previously. Loose movements persisted anywhere from one to three days and were accompanied by a sudden rise in temperature, ranging between 101° and 104° F., notably with lesions of the lower bowel. Abdominal cramps lasting several hours also occurred, especially if diarrhea was present. This was undoubtedly due to the irritant effect of both the solvent and solute as previously described. Newman,¹³ in enumerating seventeen types of atypical skin lesions, visceral hemorrhages and ulcerative colitis, as well as other evidences of phenolphthalein toxicity, mentioned that even small amounts used for "pink icing on cakes, for coloring of candies, and in pink mouth washes and dentifrices" may cause these lesions.

We did not notice any skin manifestations in any of the cases, although such lesions of the fixed erythematous and multiforme types have been described by Fox,¹⁴ Wise and Abramowitz,¹⁵ Newman,¹³ and others. Eruptions due to phenolphthalein, although not very frequent, should be watched for. No evidences of renal irritation or the constant slight albuminuria after small doses of 0.05 to 0.15 Gm., described by Hydrick,¹⁶ were noted. However, this has not been confirmed by Abramowitz,⁸ Fantus and Dyniewicz,¹⁷ and others.

In a comprehensive survey of all phenolphthalein reactions reported up to 1935, Abramowitz⁸ stated the advisability of first testing a patient for susceptibility to phenolphthalein with a small dose of 0.032 Gm. (0.5 gr.) or even less. The type of idiosyncrasy that exists points toward a sensitization of the patient to the drug, especially in view of the small dosage and the occasionally long intervals between ingestion of the drug and the reactions.

Although von Vamossy¹⁸ raised objections against the existence of numerous reactions which have been accumulated to date, the evidence remains overwhelmingly in favor of their occurrence (except possibly for the presence of albuminuria), making the test further objectionable in numerous cases.

CONCLUSIONS

1. The phenolphthalein test for gastrointestinal lesions, although simple and rapid to perform, is not without many important disadvantages. The error in our series is 24 per cent for controls and 48 per cent for persons with definite gastrointestinal lesions. Other investigations concur in the high percentage of error.

2. Explanations are offered for the marked discrepancies occurring in both false positive and false negative reactions.

3. The test is definitely contraindicated in hematemesis, most cases of acute ulceration, and acute diseases of the colon or acute exacerbations of chronic ulcerative conditions. It is also valueless in cases of jaundice, cardiovascular-renal disease, and blood dyscrasias.

4. Among the toxic gastrointestinal disturbances resulting are nausea, vomiting, laxation, abdominal cramps, diarrhea, temperature elevation and, more rarely, skin manifestations.

5. The phenolphthalein test cannot be recommended as a diagnostic procedure for the differentiation of organic disease from functional disorders of the gastrointestinal tract, or between gastrointestinal disease and diseases outside the digestive system which display symptoms referable to the stomach or intestines.

LABORATORY METHODS

GENERAL

AN INEXPENSIVE POLARIZING DEVICE FOR MICROSCOPES*

HARRY A. DEROW, M.D., BOSTON, MASS.

THE study of urinary sediments of patients with renal disease, especially when massive albuminuria is present, should always include the use of a polarizing microscope to discover the presence of doubly refractile bodies (anisotropic lipoids). Nicol prisms serve excellently to convert a standard into a polarizing microscope at a cost of about \$50.00. Recently, polaroid material mounted between white optical glass was introduced as a less expensive substitute for Nicol prisms. The price of this polarizing equipment, from \$15.00 to \$30.00, may be too costly for many physicians for such specialized microscope accessories. During the past two years we have utilized the relatively inexpensive polaroid film of 3/1,000 inch thickness to convert a standard into a polarizing microscope at a cost of \$2.00. In order to enable physicians to study urinary sediments in their own laboratories by polarized light with this inexpensive medium, we are presenting our method of converting the standard laboratory microscope into one which will serve this purpose.

Polaroid film may be purchased† in four inch squares at a cost of \$4.00 each (sufficient for two microscopes). Care must be exercised in handling the film to avoid surface scratches. The eyepiece is removed from the microscope, and its outer lens mount is unscrewed. On the outer circular rim on the under-surface of the lens mount, a thin layer of clear, neutral Canada balsam is carefully applied. A circular piece of polaroid film is cut from the four inch square of a diameter just a trifle smaller than the total diameter of the rim, and is carefully applied to the rim over the balsam. After the balsam has hardened, within forty-eight to seventy-two hours, the outer lens mount is screwed into the eyepiece. The latter is replaced into the microscope and will serve as the analyzer. A wider circular piece of film is then carefully cut from the remainder of the four inch square to fit the horizontal slot under the condenser below the stage of the microscope. This larger piece of film is carefully inserted into the slot; it should not be removed thereafter. It will serve as the polarizer.

The converted microscope may be used for the usual laboratory purposes by rotating the eyepiece so that the axes of the analyzer and polarizer are

*From the Nephritic Clinic and Medical Service, Beth Israel Hospital, and the Department of Medicine, Harvard Medical School, Boston.

Received for publication, January 12, 1940.

†Polaroid film may be purchased from the Polaroid Company, 285 Columbus Avenue, Boston.

parallel. By slow rotation of the eyepiece one produces a reddish-purplish-black field (when the analyzer and the polarizer are at right angles) in which doubly refractile bodies in the urinary sediment will appear as glistening maltese crosses. Care must be exercised to distinguish these bodies from debris, crystals, etc.

Fig. 1.—Diagram of polarizing microscope showing location of polaroid film.

With the polarizing microscope, prepared according to the method described (Fig. 1), we have found doubly refractile bodies in the urinary sediments of patients with the nephrotic syndrome associated with glomerulonephritis, amyloid disease, thrombosis of the renal veins, diabetes and hypertension.

THE MEASUREMENT OF RED BLOOD CELL DIAMETER BY THE DIFFRACTOMETER*

KATHARINE EDSALL SMITH, B.S., NEW YORK, N. Y.

THE measurement of red blood cells by the diffraction or halo method was first described by Pijper¹ in 1924. He seems to have used it only in the diagnosis of pernicious anemia, as did Eve.² Because it was of simple construction and required little time it was soon to come into wider clinical use.³⁻⁵ However, there is little report of a halo method gaining popularity in this country, and only two of our textbooks^{6, 7} consider the procedure in detail.

In view of the fact that so little actual experience has been reported, we would like to present our impressions. Since July, 1936, we have been using a diffractometer manufactured by the Spenceer Lens Co. The instrument itself is very easy to use and may be attached to any monocular microscope. There is no optical mechanism involved. A small black cylinder with a pin hole in the bottom is attached in place of the objective. The eyepiece is replaced by a second cylinder with a pinhole in the top and an adjustable device on the sides for measuring the halo. The microscope mirror is adjusted to give the most light from any good lamp (see Fig. 1). The slide is inserted in a slot in the top cylinder and rests above the measurer. Either a stained or an unstained smear may be used, but the blood side should be placed down.

When one looks into the instrument he sees a white spot in the center surrounded by a yellow halo which shades into a red periphery. The two parallel black bands on the outside are adjusted so that they just touch the outer rim of the red halo. The reading is then taken from the sliding scale and compared with a conversion table to give the mean red blood cell diameter in microns.

We have done approximately a thousand determinations by this method. Every patient having even a mild degree of anemia has at least one mean cell diameter, more often he has several. Very high white counts interfere with a distinct halo; for this reason, we do not attempt readings in patients with leucemia. Occasionally polycythemia offers technical difficulties and an extreme degree of anisocytosis may blur the outline of the halo.

The success of securing an accurate reading lies in having a smear of one cell thickness. The good smears give a clear-cut halo, and it is easy to determine the exact edge of the red circle. Herein lies one of the main sources of error, for two observers may not agree on the outline and thus may obtain different readings. Table I shows how these results may vary between two people. The maximum variation between the readings of two observers using the same smear is 0.4μ , as compared with 0.3μ when the same observer used different slides. Even this slight error makes very little diagnostic difference.

*From the Presbyterian Hospital, New York.
Received for publication, January 26, 1940.

6	7.7	8.1	7.5	7.6
7	8.5	9.0	8.9	9.1
8	7.7	8.5	7.9	7.7
9	6.9	8.0	7.6	7.4
10	7.8	8.7	7.5	7.5

As a matter of interest two of us obtained mean cell diameters on the same smears by the Price-Jones and Diffractometer methods. Table II shows a difference of as much as 1.1μ with the Price-Jones method, and only 0.2μ with the diffractometer method. Needless to say, there is a vast difference in the time consumed by the two procedures, the halo method requiring only a minute or two, and the direct measuring thirty minutes or more.

The halo method may be criticized because it does not measure cell thickness. However, there are few cases of anemia in which mean corpuscular volume is more helpful in determining microcytosis or macrocytosis than mean cell diam-

eter. Technical errors may limit the accuracy of both methods proportionately. A smear preparation is much easier to obtain from the standpoint of both the patient and technician.

No claim of perfection is made for the diffractometer, but over a period of three years it has proved itself a simple means of obtaining red blood cell size within a reasonable range of error. It is an instrument which might be a real help in any hematologic laboratory.

CONCLUSIONS

1. In over 1,000 mean cell diameter determinations the diffractometer has been found to be simple, efficient, and sufficiently accurate for all clinical purposes.

2. Tables are presented to show that the errors inherent in the method are relatively insignificant.

3. The more general use of this method is suggested.

I am indebted to Miss Illyne for her technical assistance.

AN ECONOMICAL AND EFFICIENT DISTILLING DUST TRAP

LOIS M. BRAGG, A.M.T., DENISON, TEXAS

PRACTICALLY no laboratory worker has failed at one time or another to experience the need for an efficient means of keeping dust from entering the distillate in routine laboratory distillations.

For a number of months I have used one of the ordinary spiral waxed paper drinking cups, such as is usually found in almost every hospital or business institution. These cups are conical in shape, and in use the tip is simply cut off and the cup pushed up on the condenser tube with the large end down. In this manner the cup may be slipped down so that it covers the mouth of the receiving flask, thus providing a protective shield against dust.

A CONTRAST STAINING METHOD FOR HEMOSIDERIN PIGMENT IN HEART-FAILURE CELLS

ALBERT KATZ, B.S., LOUISVILLE, KY.

THE methods in use to demonstrate hemosiderin pigment offer no means of differentiating the heart-failure cells from the surrounding leucocytes. In some cases it is difficult to demonstrate these cells because no contrast staining is offered. Isolation of such cells is also difficult because the entire smear is colorless save for the stained hemosiderin pigment granules which themselves appear in unstained cells.

A new staining method here presented allows for a contrast. In the sputum or urine, or other material for examination, leucocytes appearing with heart-failure cells are counterstained by Wright's stain, and the hemosiderin takes a bright green stain. The hemosiderin pigment stands out in sharply contrasted granules against the well-stained basic blue and acidophilic red of the stained leucocytes and other cells.

Method for Staining.—(1) Make smear of sputum in usual way. (2) Air dry. (3) Fix with heat. (4) Apply a 10 per cent solution of potassium ferrocyanide and an equal quantity of tenth-normal hydrochloric acid to the slide. Flood the slide thoroughly. (5) Allow this to stand for fifteen minutes. (6) Wash in water. (7) Dry thoroughly. (8) Apply Wright's stain. (9) Add buffered water for five minutes. (10) Wash in water. (11) Dry thoroughly and examine under oil.

A NEW MODEL MOUSE CAGE

R. L. GREENE, PH.G., NOTRE DAME, IND.

A NEW type of cage provides optimum living conditions for animals, which are indispensable requisites for trustworthy experimental work in biological laboratories. Fig. 1 shows the cage and run-way ready for use except nesting material. Fig. 2 shows the nest and run-way disconnected. The length over-all is 36 inches; the run-way is 30 by 4 by 3 inches.

Fig. 1.—A, False bottom for nesting cage; B, nesting cage, $5\frac{1}{4}$ by $5\frac{1}{4}$ by 4 inches, holds 5 or 6 adult mice; C, lid giving access to run-way; D, false bottom—aluminum 30 by $3\frac{3}{4}$ inches, $\frac{1}{4}$ inch curb; E, wire fastener and door—aluminum—for closing end of run-way; F, salad holder which prevents contamination of fresh vegetables and fruits.

FIG. 2.

The black space on the side of the run-way is the feed box. The water bottle is supported by a wire eradle. The nest is supported securely and easily on the run-way by a metal strip pointing downward toward the circular opening, which engages with a vertical strip on the top of the run-way. Removal and replacement of the nest are thus made easy.

A thick mat of paper pulp—heavy blotting paper—covers the false bottom of the run-way. It is to be replaced by a fresh one as soon as it becomes soiled. This is accomplished quickly and easily by opening E, withdrawing the soiled mat and inserting a clean one. The mice prudently deposit their excreta at E, as far away from the nest as possible.

To economize laboratory floor space, the cages are supported on a rack which holds sixteen units. Forty-eight cages on three racks, housing 250 mice, would require only a small corner of a room, 4 by 11 feet.

Received for publication, January 29, 1940.

The square boxcage, shown on the floor of Fig. 3, is a standard type of cage used extensively in biological laboratories. Ventilation, sanitation and opportunity for exercise are utterly inadequate. The long run-way of the new

FIG. 3.

model gives an abundance of fresh air and unlimited chance for exercise. Note the mouse walking upside down on the ceiling of the fifth cage on the rack. The hygienic advantages of the modern cage over the old standard type are glaringly obvious. This kind of cage is admirably adapted for high school biology classes on account of the minimum amount of time required to keep the unit tidy and odorless, simply by replacement of the floor mat once daily.

A SIMPLE AND ACCURATE MICROFRAGILITY TEST FOR MEASURING ERYTHROCYTE RESISTANCE*

A COMBINATION MICROHEMOPIPETTE METHOD

KATSUJI KATO, PH.D., M.D., CHICAGO, ILL.

NUMEROUS methods have been devised and revised for the purpose of testing the resistance of the red blood cells to various hemolytic and hemotoxic agents. Quantitation of hemolysis may be expressed in terms of any of the following criteria: (1) the depth of red color due to dissolved hemoglobin developing in the hemolytic media in which the erythrocytes have been suspended; (2) the percentage volume of the unhemolyzed corpuscles, as determined by the hematocrit method after centrifugation, since the hypotonic solutions cause the cells to expand until the maximum distensibility (the "critical" volume) has been obtained; or (3) the number of intact erythrocytes remaining in the hemolytic solutions, as enumerated by the hemocytometer method. These criteria may be used singly or in combination.

Each of the above-mentioned methods of measurement possesses its own merit and yields satisfactory results in the hands of experienced observers who have mastered its technical details. The simplest and perhaps the most reliable criterion, however, appears to be the one which estimates the degree of hemolysis by the tintorial density of the red supernatant fluid resulting from the presence of varying amounts of hemoglobin liberated from ruptured corpuscles. This is the oldest principle of the test as first devised by Hamburger (1883) and adapted for clinical use by von Limbeck (1896) and by Ribierre (1903). Because of its simplicity and accuracy, this method, with repeated modifications by Theobald Smith (1904), Karsner and Pearce (1912), Hill (1915), Giffin and Sanford (1919), Fontaine (1921), Daland and Worthley (1935), and Beebe and Hanley (1936), is still today most extensively used.

The hematocrit method, first thoroughly investigated by Hamburger (1902) and simplified by van Allen (1925) and his followers, particularly Silvette (1927) and Guest and Wing (1939), is unsatisfactory unless accompanied by other criteria, since the estimation of packed cell volume often yields doubtful results, primarily because of the presence of "ghost" cells and of unavoidable errors arising from differences in the speed and duration of centrifugation. This is particularly true when determinations are to be made on patients with severe anemia accompanied by oligocythemia.

Enumeration of intact erythrocytes remaining in the hypotonic solutions of varying concentrations is also an old method, first proposed by Chanel

*From the Department of Pediatrics, University of Chicago.
Received for publication, February 17, 1940.

(1880) and later refined by Simmel (1923), Leake and Pratt (1925), Waugh and Chase (1928), and Whitty and Hynes (1935). This method may be accurate, but the presence of hemolyzed cells with intact stroma among the truly unhemolyzed cells may lead to confusing results. Moreover, the use of a counting chamber for each concentration of salt solutions is time-consuming, and the preparation of hypotonic solutions, as devised by Simmel, is complicated. To overcome this defect, Harvey (1937) proposed the use of only one pipette and a standard hypotonic diluent of 0.35 per cent solution of sodium chloride.

A variety of hemolytic and hemotoxic substances have been employed to induce hemolysis for testing the erythrocyte resistance. The agent longest in use is sodium chloride in different concentrations, this having been first utilized by Johannes Duncan in 1867 and by Malassez in 1872, and in 1900 Vaquez pronounced a scale consisting of gradually increasing dilutions to be the "ideal method." Other substances used for the purpose are sodium oxalate, sodium sulfate, saponin, and sapotoxin, as well as other vegetable and animal poisons. The stock solution recommended by Simmel contains sodium chloride, potassium chloride, magnesium chloride, calcium chloride, sodium biphosphate, and sodium bicarbonate. Another method, employed by Theobald Smith (1904), and by Wiseman and Bierbaum (1932) is that of using diluted serum or plasma obtained from the blood samples to be tested for erythrocyte fragility. The Grancher's serum used by Chancel contained one gram of sodium sulfate in 40 c.c. of serum.

The hemolytic action of these various substances upon erythrocytes differs according to physical and chemical characteristics. Certain chemicals (benzene and indol) cause the cell membrane to become more permeable, while others (sugar and lecithin) increase the resistance of erythrocyte stroma. The presence in the blood serum of inhibitory or accelerative substances is also an important factor in understanding the mechanism of hemolysis in vitro as well as in vivo.

Nearly all the methods mentioned, except the hematocrit method, require the use of venous blood, a feature which offers a decided obstacle in testing the fragility of red blood cells in small infants. The method herein described is an attempt to reduce the technique of erythrocyte fragility test to its simplest terms by using only six different concentrations of hypotonic sodium chloride solutions and the least possible amount of capillary blood. Incidentally, it must be emphasized that the micromethod here described, because of the exactness required in mixing the saline with distilled water in correct proportions, yields results that are far more accurate than any of the prevailing macroscopic methods.

DESCRIPTION OF THE MICROFRAGILITY TEST

Instruments and Utensils Required for the Test.—For the performance of the microfragility test a set of six combination microhemopipettes* with metal holders (Kato, 1938) are used. The hypotonic solutions are prepared from 0.9 per cent solution of chemically pure recently dried sodium chloride in distilled water, the dilutions being made according to the proportions recommended

*Combination microhemopipettes and metal holders are manufactured by the Fisher Scientific Co., Pittsburgh, Pa.

in Table I. For obtaining the blood sample (see below) a hanging-drop slide with a central well (14 mm. in diameter and 3 mm. in depth) is employed.* For mixing the blood with hypotonic solutions a white porcelain spot plate provided with twelve depressions is most useful, since the entire series of dilutions can be prepared in rapid succession.

TABLE I

GRADUATED SCALE OF CONCENTRATIONS OF SODIUM CHLORIDE SOLUTION
RECOMMENDED FOR USE IN MICROFRAGILITY TEST

PIPETTE NO.	NaCl (0.9%) (c.mm.)	DISTILLED WATER (c.mm.)	OXALATED BLOOD (c.mm.)	SALT CONC. (c) (%)	NORMAL HEMOLYSIS SPAN
	30	18	12	0.630	Goat
	29	19	12	0.615	
	28	20	12	0.600	
	27	21	12	0.585	
	26	22	12	0.570	
	25	23	12	0.555	Rabbit
	24	24	12	0.540	
	23	25	12	0.525	
	22	26	12	0.510	
	21	27	12	0.495	
	20	28	12	0.480	Man
	19	29	12	0.465	
1	18*	30	12	0.450	
2	17*	31	12	0.435	
3	16*	32	12	0.420	
4	15*	33	12	0.405	Man
	14	34	12	0.390	
	13	35	12	0.375	
5	12*	36	12	0.360	
	11	37	12	0.345	
6	10*	38	12	0.330	
	9	39	12	0.315	
	8	40	12	0.300	
	7	41	12	0.285	
	6	42	12	0.270	
	5	43	12	0.255	

*Indicates the most important concentrations which must be included in the test.

The total amount of hypotonic salt solution in all the concentrations tabulated above is 60 c.mm., allowing 10 c.mm. for loss incident to manipulation.

The salt concentration (C) of any mixture may be calculated from the equation:

$$\frac{0.9\% \text{ NaCl (c.mm.)} + \text{Blood (c.mm.)}}{60} \times 0.9 = C$$

Obtaining Blood Samples.—Capillary blood is obtained from a deep skin puncture in the usual manner and is brought immediately into contact with either dry heparin powder or double oxalate mixture, the latter of which will enable the observer to use the same sample for testing the prothrombin clotting time if indicated (Kato, 1940). The proportion of either anticoagulant to the amount of blood sample should be in the neighborhood of 1:500. In this proportion these anticoagulants exert a negligible influence upon the osmotic equilibrium of the blood cells and produce no alterations on the packed cell volume. Thus, for the performance of microfragility test approximately 0.2 c.c. of capillary blood is received into the well of a hanging-drop slide, containing 0.4 mg.

x. y. *Hanging-drop slides (culture slides) can be obtained from Clay-Adams Co., New York.

of an anticoagulant. This amount of anticoagulant can be accurately delivered by introducing 20 c.mm. of a 2 per cent solution. The double oxalate solution has the following composition:

Potassium oxalate	0.75 Gm.
Ammonium oxalate	1.25 Gm.
Distilled water	100.00 c.c.

The heparin solution of similar concentration is made from crude heparin in distilled water.

The blood sample prepared according to the foregoing method is then placed in a moist chamber until the test is performed.

Preparation of Erythrocyte Suspensions.—To prepare the suspensions of erythrocytes in hypotonic solutions, the specified amount of 0.9 per cent stock solution of sodium chloride is first drawn up into a combination microhemopipette and carefully expelled into one of the depressions of a spot plate. Using the same pipette, the distilled water, also in the corresponding specified amount, is measured out and added to the saline. The two reagents are then gently but thoroughly mixed by alternately drawing up and expelling the mixture in the bore of the pipette. Finally, with the same pipette the specified amount of well-homogenized blood is thoroughly mixed with the hypotonic solution, and the resulting suspension is at once drawn up to the top mark (50 c.mm.) of the pipette, thus avoiding any waste of the suspension. The total amount of suspension, prepared according to the proportions recommended in Table I, is exactly 60 c.mm., allowing for loss of approximately 10 c.mm., which usually adhere to the surface of the utensil during the preparation of the mixture. This manipulation requires a little skill which, however, can be mastered easily after a few trials. If the blowing force is too strong, bubble formation in the mixture will invariably cause a shortage of the suspension to fill the pipette to the top mark. If too much of the suspension is lost in this way, or in any other way, a new one must be prepared to insure uniform results, especially with reference to the cell volume in each pipette.

After the suspension is drawn up to the top mark, the two ends of the pipette are at once closed by immobilization in the metal holder, and correctly labeled according to the number corresponding to each dilution. The same process is repeated for each concentration of salt solutions. After the entire series of dilutions have been prepared, they are left in horizontal positions on a flat surface and allowed to remain so for at least one hour, occasionally reversing the positions of the pipettes to permit the complete hemolytic action of solutions upon the suspended erythrocytes. The pipettes in their metal holders are then centrifuged for ten to fifteen minutes at 2,500 r.p.m. The supernatant fluid in each pipette and the cellular layer at its bottom may now be observed as to the extent of hemolysis.

Recording the Results.—The concentrations recommended for the series of six pipettes used in the microfragility test have been selected to include only the two critical ranges; namely, the range in which initial hemolysis normally occurs (first four pipettes) and the range in which complete hemolysis is most frequently observed (last two pipettes). For normal human blood beyond in-

fancy the concentration at which initial hemolysis occurs is usually 0.435 per cent (the second pipette), and occasionally 0.420 per cent (the third pipette), and complete hemolysis is 0.330 per cent concentration (the last pipette). These two critical concentrations can be used to designate the span of hemolysis, conveniently recorded as 0.435/0.330. Undoubtedly, even under normal conditions slight variations may occur, but the selection of the two critical ranges recommended is based upon experience gained in performing a large number of tests on normal human blood. If too great a deviation is found in either direction, a repetition of the test is necessary by changing the scale of concentrations in whichever direction indicated.

TABLE II
AVERAGE NORMAL FRAGILITY OF HUMAN ERYTHROCYTES
(Microfragility Test)

PIPETTE NO.	SALT CONC. (%)	DEGREE OF HEMOLYSIS	VOLUME OF GHOST CELLS (C.MM.)	VOLUME OF INTACT CELLS* (C.MM.)
1	0.450	0	0	5.0
2	0.435	±	0.1	5.5
3	0.420	+	0.5	6.0
4	0.405	++	1.0	5.0
5	0.345	+++	Indistinct	2.0
6	0.330	++++	Invisible	0

*The figures in this column represent the values of packed cell volume of unhemolyzed erythrocytes in actual number of cubic millimeters after centrifugation (compare with Fig. 1). Since these values depend upon the percentage volume of packed erythrocytes in undiluted whole blood, the volume in each diluted specimen may be more accurately expressed in relative percentage of the packed whole cell volume.

In recording the degree of hemolysis the depth of the red color, due to the presence of dissolved hemoglobin, affords the most reliable criterion, but the packed erythrocyte column found at the bottom of the pipette also yields valuable information (Table II). In the second pipette, in which initial hemolysis normally occurs, the red color of the supernatant fluid may be so slight that its detection may require a careful comparison with the first pipette in which hemolysis is negative. But a trace of hemolysis in the second pipette is almost invariably accompanied by the presence of a very thin layer of transparent hemolyzed cells, the so-called "ghost" cells, overlying the packed intact erythrocytes. As the concentration of the salt solution decreases, the "ghost" cell layer will be seen to increase in proportion to the augmenting intensity of the red color in the supernatant fluid. At the same time there is a gradual decrease in volume of opaque intact erythrocytes after having increased at initial hemolysis, until complete hemolysis is reached, at which point there is no demonstrable column of intact cells and the red color of the solution is so intense that the "ghost" cells are completely obscured (Fig. 1). The percentage volume of opaque unhemolyzed erythrocytes in each pipette after centrifugation may also be recorded in comparison with the packed cell volume of the whole blood, but owing to certain unavoidable errors in dealing with a small amount of blood such as recommended for the microfragility test here described, the observation of the cell volume alone does not yield consistent results of any particular value.

Attempts at exact quantitation of hemolysis by use of a colorimeter employing standard solution of hemoglobin for comparison have been made by

some observers, particularly Lapieque and Vast (1899), Lepeschkin (1932), and Waugh and Asherman (1938), but such procedures appear to be entirely unnecessary inasmuch as the quantitative estimation of liberated hemoglobin is not the primary object of the test. For practical clinical purposes it is quite sufficient to indicate the range of hemolysis by simply noting the concentrations of salt solution in which hemolysis begins and ends, in the manner indicated in Table II.

Degrees of Hemolysis

Fig. 1.—Six combination microhemipipettes (1-6) used in the microfragility test. No the absence of hemolysis in the first pipette and complete hemolysis in the last pipette. The maximum cell volume is obtained in pipette 3 and the initial hemolysis is seen in pipette 2.

COMMENT

The microfragility test here described is an attempt to simplify the more commonly used method for measuring the resistance of erythrocytes to hypotonic solutions of sodium chloride. Three distinct advantages of this test are: (1) simplicity in technical manipulation; (2) small amount of blood required for the test; and (3) accuracy attained by the use of graduated microhemipipettes which facilitate the exact observation not only of the degree of hemolysis in the supernatant fluid, but also of the volume of hemolyzed cells which overlies the column of opaque intact erythrocytes. The microfragility test may be most conveniently used in pediatric practice and in hematologic research on small experimental animals.

According to the results obtained from observations on a number of normal human beings, the microfragility test reveals the average initial hemolysis that occurs at the sodium chloride concentration of 0.435 per cent and the co

plete hemolysis at 0.330 per cent, giving an average of 0.1 per cent as a normal hemolysis span. Slight variations may be found from time to time, but under normal conditions the resistance of human erythrocytes against hypotonic salt solutions remains remarkably constant. Any significant deviation from the normal range mentioned, especially in the point of initial hemolysis, usually indicates the presence of erythrocyte anomaly and calls for repeated observations. A few examples of instances in which abnormal fragility has been found are summarized in Table III.

TABLE III
ABNORMAL FRAGILITY IN VARIOUS CONDITIONS

DISEASE	R.B.C. (MILLIONS)	HB. (GM. %)	PACKED CELL VOLUME (%)	CORPUSCLE VOLUME (CM)	ICTERIC INDEX (MURPHY UNITS)	INITIAL HEMOL- YSIS (% CONC. NaCl)	FINAL HEMOL- YSIS (% CONC. NaCl)

normal newborn	5.09	16.0	55	108	20	0.525	0.330

One of the most important clinical conditions in which the test proves to be most useful is in jaundice so frequently seen in various types of liver disease and blood dyscrasias. Since Chauffard in 1907 first demonstrated the increased fragility of erythrocytes in congenital hemolytic jaundice, numerous observers have confirmed this striking phenomenon. In one instance of this disease the microfragility test performed during a remission disclosed only a slight increase in erythrocyte fragility, namely, 0.450/0.375 per cent, indicating a definite shortening of the span of hemolysis. In a case of moderately severe catarrhal jaundice with pronounced bilirubinemia (van den Bergh 15 units) the initial hemolysis occurred at a normal concentration (0.435 per cent), but the hemolysis was not complete until the concentration reached an abnormally low level (0.255 per cent), indicative of a great prolongation of the hemolysis span. During the terminal stage of a case of acute leucemia with a marked anemia (erythrocyte count 1,560,000) and extreme leucopenia (leucocyte count 900), there was a slight increase in erythrocyte resistance (0.405/0.315 per cent). Practically identical results in fragility tests were obtained in a case of moderately severe posthemorrhagic anemia (erythrocyte count 3,540,000) in a 7-year-old child. In a case of rheumatic carditis in a quiescent stage erythrocyte fragility was slightly decreased (0.450/0.360 per cent), while in one instance of advanced rheumatoid arthritis with a pronounced anemia (erythrocyte count

1,810,000) an abnormal increase in erythrocyte resistance (0.390/0.285 per cent) was noted. In normal newly born infants it is customary to find a distinct increase in erythrocyte fragility (average 0.510/0.300), a phenomenon which satisfactorily explains the pathogenesis of physiologic jaundice of the newborn.

The most remarkable instance of greatly increased erythrocyte fragility was seen in a newborn infant with erythroblastosis fetalis (*icterus gravis neonatorum*) with a high icteric index (150 Murphy units). The microfragility test performed toward the end of the first twenty-four hours of life revealed

Fig. 2.—Hemolysis spans of erythrocytes in a case of erythroblastosis fetalis (*icterus gravis neonatorum*). Note increased fragility with prolonged hemolysis spans during the first five days of life and gradual return to the normal span upon recovery.

initial hemolysis at a concentration of 0.630 per cent and complete hemolysis at 0.375 per cent (Fig. 2). Upon repeating the test on subsequent dates, it was found that erythrocyte resistance gradually increased so that by the fourteenth day of life the cells began to hemolyze at a concentration slightly above the limits of normal range. Incidentally, it is to be noted that the gradual decrease in erythrocyte fragility in this infant coincided with the decrease in the percentage number of nucleated red blood cells, which on the first day of life was as high as approximately 75 per cent of the total nucleated blood cells.

These findings, though purely accidental, throw some light on the pathogenesis of extreme jaundice so characteristic of this disease. *Icterus neonatorum*, both physiologic and pathologic, has been the subject of repeated investigations by numerous observers, but as yet no conclusive evidence of its underlying etiology has been demonstrated. The accidental findings here recorded suggest very strongly the possibility of increased erythrocyte fragility, with consequent

bilirubinemia as being the fundamental cause of jaundice in the newborn. Moreover, in all probability, this increase in fragility is due to the rapid destruction of nucleated red blood cells which are so abundantly found in various organs as well as in the peripheral blood. The severity of jaundice appears to be in direct proportion to the increase in erythrocyte fragility, since erythrocyte fragility in normal newly born infants with physiologic type of icterus is only slightly increased and never to the extent seen in icterus gravis neonatorum. A more complete investigation of erythrocyte fragility in the newborn will be given in a later report.

FRAGILITY OF MAMMALIAN AND AVIAN ERYTHROCYTES

The fact that the resistance of erythrocytes against hemolytic agents is specific not only in each species of animals, but also in different individuals of the same species, was conclusively demonstrated by Hamburger (1902). The results of observations obtained by means of the microfragility test performed on the blood of mammals and birds, summarized in Table IV, reveal a great variation in erythrocyte fragility in the different species.

TABLE IV
MICROFRAGILITY TEST IN MAMMALS, PIGEON, AND MAN

SPECIES	AVERAGE NORMAL R.B.C. (MILLIONS PER C.MM.)	PACKED CELL VOLUME (%)	CORPUSCULE VOLUME (μ)	INITIAL HEMOLYSIS (% CONC. NaCl)	FINAL HEMOLYSIS (% CONC. NaCl)
Oat	16.00	55	34.5	0.615	0.480
Sheep	7.50	33	44.0	0.600	0.450
Rat	7.00	50	71.4	0.480	0.375
Rabbit	5.00	40	72.7	0.570	0.450
Mouse	10.00	80	80.0	0.535	0.330
Dog	6.50	55	84.6	0.450	0.360
Guinea pig	5.50	50	91.0	0.450	0.330
Pigeon	2.75	33	120.0	0.465	0.360
Man (infant)	6.00	55	90.0	0.510-0.450	0.315-0.300
Man (child)	4.00	35	88.8	0.435	0.330
Man (adult)	5.00	45	90.0	0.420	0.330

Data on the fragility tests in animals demonstrate the definite relationship existing between the volume as well as the shape of the red blood cells and their degree of resistance against hypotonic salt solutions. The fact that the fragility parallels the diameter of the cells was first noted by Vallery-Radot and Lehritier (1919), while Castle and Daland (1937) proved that differences in the susceptibility of various types of erythrocytes to hemolysis are due principally to differences in form and not to differences in osmotic behavior. Haden (1939), in numerous and painstaking studies of the peculiarities of erythrocytes in congenital hemolytic icterus, concludes that spherocytosis, which is so characteristic of this disease, is the essential factor in increased fragility.

In this connection it is also of interest to note the striking observation recorded by Rywosch (1907), namely, that the hemolytic action of hypotonic saline upon the resistance of mammalian erythrocytes exhibits a reverse of their resistance to saponin. Ponder, Saslow, and Yeager (1930), in re-examining a large number of resistance series of erythrocytes from various animals, have

proposed the hypothesis that in any hemolytic system certain physicochemical changes take place which affect the permeability of cell membranes, specific to the erythrocytes of each species and giving rise to different resistance series.

The increased fragility of erythrocytes in pigeons, in spite of their high mean corpuscular volume, requires separate consideration, inasmuch as their red blood cells are all nucleated.

SUMMARY

A new microfragility test, utilizing the same principle as that originally employed by Hamburger and used for clinical purposes by von Limbeck and by Ribierre, and later modified by numerous workers, particularly Giffin and Sanford, but greatly simplified and especially adapted for use in small infants and animals, is described.

As tested by this method, initial hemolysis of normal human erythrocytes is found to occur at an average of 0.420 to 0.435 per cent concentration of sodium chloride solution, while complete hemolysis is most frequently seen at 0.315 to 0.330 per cent concentration. The normal range or span of hemolysis is thus approximately 0.1 per cent concentration. The simplicity and accuracy of the test are the features especially adapted to routine hematologic examination.

A few illustrative examples of the results obtained by this method in various diseases characterized by abnormalities in erythrocyte fragility are reported. The striking increase in erythrocyte fragility in a case of erythroblastosis fetalis (icterus gravis neonatorum), as revealed by the microfragility test, suggests the fundamental mechanism in the causation of icterus in the newborn.

The normal hemolysis ranges of erythrocytes in a few mammals and pigeons, as measured by the microfragility test, are also recorded in this preliminary report.

CHEMICAL

THE USE OF OSTEOTROPIC DYES IN A MODIFIED LINE TEST FOR VITAMIN D*

GUSTAV J. MARTIN, Sc.D., NEW YORK, N. Y.

THERE are three methods for the estimation of vitamin D: the estimation of the ash content of bones (humerus or femur);¹ the line test;² and the x-ray examination of bones.³ The determination of ash content has never received wide acceptance, as it is a much more tedious process than the line test. Hume and co-workers⁴ evaluated this technique and found that when the percentage of ash was plotted against the logarithms of the doses, a linear relationship between the two variables was revealed, showing that as the doses were increased in geometrical progression the calcification increments advanced in arithmetical series. It is an excellent method but, for practical reasons, it is difficult to apply.

The x-ray technique was studied by Bourdillon and associates,⁵ who attributed such an increased accuracy to the method that they listed twelve different degrees of healing in rachitic rats. Compared to the bone ash method, radiographic comparison is equally accurate, and because it is easier to apply it is the better of the two methods.

The line test is the more generally accepted procedure because it is inexpensive, requires no special apparatus, and presents no technical difficulties. Bills and others⁶ in a "critique" of the line test, state that by using 100 animals the error is reduced to 4 per cent. The line test depends upon the conversion of silver phosphate to black colloidal silver following exposure to light. Bills lists the different types of healing as the epiphyseal, in which new calcium is laid down in a narrow line at the distal edge of the cartilage; the metaphyseal, in which deposition occurs at the metaphysis; and the diaphyseal, in which the first calcification is diaphyseal and contiguous with the trabeculae that remain after rickets develops. The latter is useless for the line test. The line test is most delicate, since it detects very early stages of healing which x-ray will not show. Bone, whether newly deposited or not, gives the reactions involved in the silver method. Deposition of bone when it does occur is not necessarily along the line of calcification examined in the line test. These facts frequently complicate the accurate diagnosis of a bone section.

As uncalcified tissue will not stain with hematoxylin, and calcified tissue will, a method of hematoxylin staining has been used, but, again, there is no differentiation between the newly formed and the old bone.

Gottlieb⁷ suggested the use of alizarin and purpurin in the staining of newly formed bone. The suggestion was made that the mechanism involved the local

Received for publication, January 18, 1940.

concentration of calcium ions. The use of alizarin and of purpurin was studied by Cameron,⁸ who injected sodium alizarin sulfonate in a 2 per cent solution. Bones started developing the color in five minutes and became most intensely colored in twelve hours. Anthrapurpurin and purpurin gave less pronounced results. Cameron used the method in studying fracture callus in the rat. The callus was unstained at ten days, deeply stained from ten to sixty days, and practically unstained thereafter. Alizarin was also used to stain the calcified areas produced by hypervitaminosis D. A method used by Brash⁹ consists of feeding madder and then stopping the administration so that new bone growth is white, while all bone formed during the madder feeding period is stained from pink to red. This seemed to be the clue to a highly specific line test modification. The mechanism of the osteotropic dye is suggested by Ercoli¹⁰ to be an adsorption phenomenon. The sodium alizarin sulfonate is irreversibly fixed and a red complex is formed. Phosphate ion is liberated in this mechanism.

EXPERIMENTAL

Sodium alizarin sulfonate, a water-soluble derivative of alizarin, is recommended by Cameron⁸ for its osteotropism. We administered 1 c.c. of a 2 per cent solution to 60 Gm. rats and found we were above or at the fatal dose. The dosage was cut to 0.2 c.c. of 2 per cent sodium alizarin sulfonate and found to be harmless, but it gave no distinct coloration to the bones. The compound showed no marked osteotropism, probably because of its water solubility.

Next, a 2 per cent suspension of alizarin in water was used. One cubic centimeter each was injected intraperitoneally into 20 rats. No bone coloration was observed in any of the supplemented animals. Here the complete insolubility of the alizarin prevented its being effective. Examination of the peritoneal cavities of these animals showed unabsorbed dye in large amount.

Finally, sodium alizarinate was used in a 1 per cent solution in water at a pH of 8.0. In one experiment of twenty-four-hour duration, 1 c.c. of the 1 per cent sodium alizarinate solution was injected intraperitoneally. At the same time, supplements containing varying amounts of vitamin D in oil were given orally. Twenty-four hours later the animals were killed, and the radii and ulnae were removed, split lengthwise, and examined microscopically. The negative controls showed no coloration or a faint pink tinge, indicating the absence of new bone formation. If any coloration is seen, it is generally disseminated, coloring the entire bone and assuming no definite pattern, a state such as occurs following new calcium deposition. Three rats receiving a total of 0.3 units of vitamin D showed 1+ and 2+ healing by our scale. The calcium deposition may occur along the line of calcification in the epiphysis or the diaphysis, and yet distinct coloration, which can be used in assigning a value of healing, is observed. Three rats receiving a total of 1 unit of vitamin D showed a 2+ and 3+ healing. As the bones are semitransparent, it is possible to observe macroscopic differences in color intensity without cutting them. It is possible that a twenty-four-hour test can be developed, using macroscopic examination.

Ten rats were used in a two-day test. One cubic centimeter of 1 per cent sodium alizarinate was given intraperitoneally on the first day to all rats. Six-

tenths unit of vitamin D was given to the supplemented animals in two doses of 0.3 unit each. Forty-eight hours after the first dose of vitamin D was given, the animals were killed and the bones were examined. Values of 3+ and 4+ were assigned to the degree of healing seen.

Arbitrary values are assigned to divide into six divisions, from 0 to 6, the range of healing from absence of coloration with no vitamin D to the coloration of the bone at complete healing. A value of 6 indicates complete healing. Chart I illustrates these stages of healing.

A series of tests was conducted, using both the silver staining² and the alizarin techniques. The results are recorded in Table I. This table shows a more uniform result where alizarin was used. In this group the sodium alizarinate was given intraperitoneally on the date of the first dosage with vitamin D, and the bones were examined forty-eight hours later.

The second series of sodium alizarinate animals was given intraperitoneal dye (1 c.c. of 1 per cent) after the third dosage of vitamin D in a series of five daily doses. The bones were removed and examined on the sixth day. An improved coloration was noted which, compared to the silver line test, gave the results in Table II.

A third series for comparison was conducted by giving the sodium alizarinate (0.3 c.c. of 1 per cent) on three different occasions: at the time of the first vitamin D supplement, on the third day, and when the final dose (fifth day) of vitamin D was given. The group showed no material improvement over the second series in accuracy, and the additional administrations are, therefore, regarded as unnecessary. The results of this smaller group are recorded in Table III.

DISCUSSION

Cameron⁸ has pointed out that alizarin is a nearly specific stain for calcium. It reacts readily in vitro or in vivo with recently deposited calcium salts, either normal or pathologically formed, but it fails to stain older deposits. Silver nitrate is not a test for calcium or phosphate; the black reaction is given by a variety of solids, the anion being more important than the cation. As pointed out by Bills and associates,⁶ deposition of calcium following administration of vitamin D may not occur along epiphyseal or diaphyseal lines, and, if it does not, the silver line test is useless. Hematoxylin does not stain calcium salts, though it often identifies areas in which changes favorable to the deposition of calcium salts are taking place. Alizarin stains only newly formed bone. It stains these calcium deposits whether they are epiphyseal, diaphyseal, or metapiphyseal. It follows that greater specificity, greater applicability, and greater speed result from the use of alizarin.

SUMMARY

A modified line test involving the use of an osteotropic dye, alizarin, is introduced. Greater specificity, greater applicability, and greater speed result from its use.

RECOVERY OF CARBON TETRACHLORIDE FROM TISSUE*

IONE WEBER, S.B., M.A., PH.D., BROOKLYN, N. Y.

THE difficulty encountered by Gettler and Siegel¹ in the recovery of pure carbon tetrachloride after addition to tissue seemed to me to be due to the heating of the carbon tetrachloride in the presence of tissue. The first step in their method is steam distillation. While they were able to recover the carbon tetrachloride by rectification after steam distillation of carbon tetrachloride in water, the method failed when applied to carbon tetrachloride added to tissue. In the latter case a part of the carbon tetrachloride was converted to chloroform. To obviate heating, the method here described was devised.

THE APPARATUS

The apparatus is shown in Fig. 1. The ground glass joints connecting *A* and *B*, and *B* and *C* are 45-50. The tube *D* is a Gettler collection tube^{1, 2} sealed into the bottom of *C*. This collection tube is 13 cm. long, has a diameter of 0.7 cm., and a capacity of 3 c.c. graduated in twentieths. By means of rubber vacuum tubing *E* is connected to two glass traps in series. The second trap is connected through an ordinary closed-end mercury manometer to a vacuum pump.

Flask *A* is supported by a condenser clamp at the neck, and *C* is prevented from falling by copper wire fastened tightly around the neck of *C* and coiled loosely about the horizontal portion of *B*. The usual glass hooks sealed in above and below the glass joint and rubber bands may also be used.

*From the Chemistry Department of Brooklyn College, Brooklyn.
Received for publication, July 27, 1940.

PROCEDURE

The distillation flask *A* was immersed to the bottom of the neck in dry ice and acetone contained in a large Dewar flask. Some glass wool had been placed in the Dewar to prevent spontaneous overflowing. Half of the tissue, ground lamb's brain, was introduced into *A*. The temperature of the carbon tetrachloride was taken (room temperature). It was introduced by means of a pipette graduated in hundredths. The second half of the tissue was then introduced. After the ground glass joints had been greased with Lubriscal, *B* and *C* were attached, and the stopcock in the side arm of *B* was closed, *E* was connected to the first trap, and the tissue and carbon tetrachloride were allowed to freeze for the length of time indicated in Table I.

Fig. 1.—Apparatus for distillation and measurement of recovered liquid.

Each of the two traps was immersed in a Dewar containing dry ice, acetone, and glass wool; the stopcock in the side arm of *B* was opened and the vacuum pump was turned on. The pump was allowed to run for about ten minutes after the minimum pressure was attained, which averaged about 0.5 mm. The stopcock was closed and the rubber tubing was disconnected.

The large Dewar containing dry ice and acetone was shifted from *A* to *C*, the level of the liquid being adjusted to the midpoint of the bulb *C*. The flask *A* was immersed to the bottom of the neck in water at about 25° C., and the distillation was allowed to run for the length of time indicated in Table I. At the end of the distillation the stopcock was opened to allow the pressure inside to come to that of the atmosphere, and then closed. The apparatus was then raised so that only the lower half of the collection tube *D* was immersed in the dry ice

and acetone. When all the solid in *C* had melted, *C* was disconnected at the ground glass joint, stoppered with a cork, and the collection tube immersed in water and kept at the temperature at which the carbon tetrachloride had been measured until no change in volume could be observed. The amount of the distilled water above the carbon tetrachloride varied from 0.05 to 2 c.c. In spite of scrupulous cleaning, first with soap and water and then with chromic acid or concentrated nitric acid and drying in an oven, the bulb *C* always contained droplets of moisture at the end of the melting. After water was dropped into *C* to wash this moisture into *D*, additional carbon tetrachloride was sometimes recovered.

The recovery in cubic centimeters and percentage is given in Table I. The purity was determined by the microboiling point, Siwoloff's method,³ and the refractive index of the carbon tetrachloride layer. The boiling point of the original carbon tetrachloride was determined at as near the same pressure as was practicable. The refractive indices were corrected for temperature by applying the general rule: refractive index decreases 0.0004 per degree Centigrade rise above 20°.

All recovery samples and the original were tested for chloroform in carbon tetrachloride by the cyclohexanol, alpha-naphthol, potassium hydroxide method.⁴ Each gave a negative result.

A small amount of frost always appeared in the glass traps. The rate of evaporation on warming to room temperature suggested water. On only one occasion was there a sufficiently large drop for a boiling point determination. In this case it was water.

Putrefaction of the tissue apparently does not affect the purity of the distillate. In determinations 1, 4, and 17 in Table I, the tissue was very putrid, and in many other cases it was several weeks old.

DISCUSSION

I believe some carbon tetrachloride is lost during its introduction into the distilling flask. There is always a strong odor of carbon tetrachloride during this process. Also, while calibration of the collection tube against the pipette using mercury shows a check to 0.01 c.c., the transfer of 1 c.c. of carbon tetrachloride from the pipette to the collection tube at room temperature shows a loss of 0.025 c.c. It may be possible that the carbon tetrachloride present in tissue poisoned in vivo may be frozen at a low temperature, the tissue ground and introduced before thawing sets in, and the carbon tetrachloride recovered with less loss. It is also possible that some carbon tetrachloride is vaporized during the melting, or that some remains in the distillation flask.

The method should be adaptable for use in isolating ether or any other liquid immiscible with water which boils below 100° C. from tissue or other similar mixtures.

SUMMARY

A low temperature, low pressure distillation method for the recovery of carbon tetrachloride after addition to tissue is described.

A SIMPLIFIED MICRO TEST OF PLASMA PROTHROMBIN*

JOHN E. KARANIN, M.S., M.D., AND EDWARD R. ANDERSON, M.S., M.D.
CHICAGO, ILL.

A SIMPLIFIED micro test of plasma prothrombin based on the principles of the Smith test has been found to be as accurate as the Smith test used by us for the determination of the prothrombin clotting activity of the blood. A useful micro Quick test has been devised by Kato¹ but it is as complicated as the Quick method² because of the number of steps and ingredients involved in the test. However, as in the Smith method,³ the simplified micro test as herein suggested depends upon the use of only blood and thromboplastin. Utilizing the principle of the Smith test, the micro test was investigated and was found to be surprisingly accurate and simple to perform. The test was done on patients suspected of having a hypoprothrombinemia and checked by the Smith method. The results were recorded in per cent of prothrombin clotting activity (Tables I and II).

The micro test is performed in the following manner: A puncture wound is made in the ear, finger, or heel, and with a Kato microhemopipette 30 to 40 c.mm. of blood are drawn into the tube. This is transferred immediately to a watch glass and mixed with 10 c.mm. of thromboplastin.† The glass is tilted back and forth until a clot is formed. The time recorded for the formation of the clot is divided into the control prothrombin clotting time obtained in the same manner from a normal individual. The result is the per cent of prothrombin clotting activity of the patient. Dangerous levels are those below 70 per cent. Hemorrhage may occur when these levels are reached. The time found by this method is usually five to eight seconds longer than the time by the Smith test. However, the percentage result is as accurate as in the Smith method. The only difficulty encountered in the micro test is the determination of the end point of the clot. With practice the exact end point can be readily determined.

The advantages of the micro method are obvious. It does not require a venipuncture and necessitates very little equipment and time to perform. Since venipuncture is unnecessary, it may be done on infants without difficulty. It

†Thromboplastin is obtained from rabbit brains or lungs. Approximately 25 Gm. of the material is macerated in a mortar and mixed with about 100 c.c. of physiologic saline solution. This is allowed to stand in the icebox for three hours. The supernatant fluid is decanted and contains the active thromboplastin. The solution is kept in the icebox and is warmed to room temperature before using. If time for a normal individual is less than twenty seconds, the thromb illuded with saline so that the normal prothrombin time will be econds. The activity of the thrombo- plastin decreases daily; thus for the sample of thromboplastin used must be made on a normal st is performed on the patient.

TABLE I

COMPARATIVE PLASMA PROTHROMBIN VALUES FOR THE SMITH AND THE MICRO METHOD TAKEN UPON NORMAL INDIVIDUALS USING THE SAME THROMBOPLASTIN SOLUTION

Approximately 5 to 8 seconds difference occurs between the times of the two methods, but the percentage result is accurate for each method.

PATIENT	PROTHROMBIN CLOTTING ACTIVITY	
	SMITH METHOD	MICRO METHOD
1 Normal	26 sec. or 100%	33 sec. or 100%
2 Normal	26 sec. or 100%	34 sec. or 100%
3 Normal	28 sec. or 100%	34 sec. or 100%
4 Normal	30 sec. or 100%	35 sec. or 100%
5 Normal	31 sec. or 100%	37 sec. or 100%
6 Normal	30 sec. or 100%	37 sec. or 100%
7 Normal	30 sec. or 100%	36 sec. or 100%

TABLE II

COMPARATIVE PLASMA PROTHROMBIN VALUES IN 8 PATIENTS SUSPECTED OF HAVING A HYPOPROTHROMBINEMIA

The per cent plasma prothrombin activity as determined by the micro method is found to coincide with the clotting activity as determined simultaneously by the Smith method.

PATIENT AND DIAGNOSIS	PROTHROMBIN CLOTTING ACTIVITY	
	SMITH METHOD	MICRO METHOD
1 Choledocholithiasis	43 sec. or 72%	50 sec. or 70%
2 Choledocholithiasis	38 sec. or 71%	46 sec. or 74%
3 Choledocholithiasis	36 sec. or 84%	40 sec. or 80%
4 Choledocholithiasis	30 sec. or 100%	36 sec. or 100%
5 Cholecystitis	30 sec. or 88%	38 sec. or 88%
6 Cholecystitis	25 sec. or 84%	30 sec. or 83%
7 Carcinoma of pancreas	32 sec. or 79%	38 sec. or 80%
8 Cholelithiasis	24 sec. or 86%	32 sec. or 87%

may be done as quickly as a leucocyte or erythrocyte count, and in accuracy compares favorably with the Smith test.

The microhemopipette of Kato may be purchased from the Fisher Scientific Co., Pittsburgh, Pa.

CONSISTENT BLOOD SUGAR VALUES OBTAINED FROM RABBIT HEART BLOOD SAMPLES*

S. C. WERCH, M.Sc., M.D., CHICAGO, ILL.

THE use of the rabbit for blood sugar estimations has often been questioned. Still the animal has been used, and in most cases has furnished the required information even if the data obtained were handled conservatively. Certain objections have remained, nevertheless, and in particular the influence of excitement. Even the trained animal becomes excited during ear vein puncture for peripheral blood; and in taking heart blood under ordinary precautions, excitement nearly always occurs and internal injury frequently takes place. In order to overcome these and other well-known objections, the following technique was put into operation, and the normal blood sugar values obtained (Hagedorn-Jensen¹) were subjected to statistical analysis.

TECHNIQUE

No anesthetic or assistance is needed in carrying out the technique, but a quiet room and a rabbit board of adequate length are essential for success.

The rabbit is gently lifted by its ears onto the lower short edge of the board and is held in an upright position (Fig. 1) until loops are placed on its extremities. After its hind legs are tied close, the rabbit is slowly lowered until its back rests on the board (Fig. 2). The forelegs are slowly drawn in the direction of the head and tied. Tying is necessary to keep the animal from rolling over. These steps are facilitated if the grip on the rabbit's ears is maintained with one hand until the other has completed the tying. The animal may be kept quiet for hours if its nose is stroked at intervals, or when deemed necessary.

Heart blood should be taken only after the rabbit has been resting on its back a few minutes. A syringe with a No. 19 or 20 gauge needle has been found best. The needle is introduced from the left costal region, and the blood is withdrawn slowly. When samples are taken at widely separated intervals, the rabbit may be lifted from the board and placed in a box until needed again, without removing the ties from the extremities.

EXPERIMENTS AND RESULTS

Blood sugar estimations were made on samples procured at the following intervals: 15, 30, 60, 120, 180, and 240 minutes. Two series of experiments were done. In one series, including 25 animals, the rabbit was kept on the board in the quiet state for the entire period of four hours. In the other series, 75 animals, the rabbit was placed in a box between the intervals. The latter experiments permitted study of the effect change in position would have on blood sugar values.

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.
Received for publication, February 10, 1940.

Table I includes the mean values (m) and their respective standard deviation (σm) for the experiments during which the animal was kept supine for four hours, as well as when it was placed in a box between the time intervals. For the six intervals the mean values range between 74.12 and 77.00 mg. per cent in the first series, and between 77.70 and 81.15 mg. per cent in the second.

Fig. 1.

Fig. 2.

The greatest obtained difference, therefore, is 2.88 and 3.45, respectively. The mean of the six means of the former group is 75.45, and of the latter, 79.36, and their difference is 3.89.

DISCUSSION

Statistical study of the blood sugar values revealed fair agreement. The means obtained in the series of experiments when the animal was kept supine for four hours gave obtained differences which fell well within the range of error of the blood sugar method. This was also true when one treated similarly

the means obtained in the series when the animal was placed in a box between the intervals. Comparison of the two series indicated that one gains very little, if anything, by keeping the animal supine for a period of four hours.

TABLE I

BLOOD SUGAR VALUES IN MILLIGRAMS PER CENT OBTAINED BY THE HAGEDORN-JENSEN METHOD

INTERVALS IN MINUTES	25 RABBITS SUPINE FOR 4 HOURS		75 RABBITS NOT SUPINE BETWEEN INTERVALS	
	M	σM	M	σM
15	74.12	± 4.80	77.70	± 6.20
30	75.00	5.17	78.30	5.60
60	77.00	7.18	79.80	7.63
120	74.67	3.75	81.15	5.60
180	75.50	4.20	79.70	5.83
240	76.40	5.87	79.50	6.24

Several advantages are observed in the technique described. Skill entirely eliminates excitement in the animal. The method of handling, omission of an anesthetic, the facility with which heart blood may be taken in adequate quantities, all help furnish more accurate blood sugar values. With care the animal may be used again and again.

CONCLUSIONS

A technique is described which permits heart blood to be taken from rabbits without the need of an anesthetic or assistance and which renders consistent blood sugar values.

EFFECT OF INGESTED IRON ON TESTS FOR OCCULT BLOOD IN STOOLS*

ALLEN S. JOHNSON, M.D., SPRINGFIELD, MASS., AND ERNEST B. OLIVER, M.D., BIRMINGHAM, ALA.

IT IS not infrequently important to determine whether a patient, who is receiving iron by mouth to correct an anemia due to gastrointestinal hemorrhage, is still losing detectable amounts of blood. Tarry stools are not significant while he is ingesting iron. Inquiries, therefore, were instituted among a number of pathologists and laboratory workers to determine whether the usual chemical tests for occult blood in the stools were reliable under these conditions. The diversity of opinions suggested that actual experiment was indicated.

Since it has been found that large amounts of red meat in the diet may give a falsely positive benzidine test for occult blood in the stools, even though the guaiac test usually remains negative, seven persons were first put on a meat-free diet. After several days their stools were tested and found to give no

*From the Springfield Hospital, Springfield.
Received for publication, March 11, 1940.

reaction for occult blood with either benzidine or guaiac reagents.* Each individual was maintained on the same diet and given in addition 12 grains daily of ferrous sulfate by mouth. As soon as the stools became tarry the benzidine and guaiac tests were again applied. To our surprise the guaiac tests were repeatedly positive and the benzidine tests were consistently negative so long as the ferrous sulfate resulted in tarry stools. The iron was then discontinued and the stools were again tested for occult blood as soon as the tarry characteristics disappeared. Both benzidine and guaiac reagents once more gave negative results as before the iron was administered.

Nine other persons who were found to have both benzidine and guaiac-negative stools on the ordinary hospital diet were given daily 30 grains of ferrous sulfate by mouth. As soon as their stools became black they were found to give a positive reaction with the guaiac test but not with the benzidine test. After discontinuing the ferrous sulfate the stools of these patients gradually became guaiac negative, with the exception of one, as they lost their tarry appearance. This patient continued to produce stools that gave a positive reaction as late as five days after the tarry color had disappeared. The nine patients who had received double the usual therapeutic dose of ferrous sulfate did not produce guaiac-negative stools until several days after the excreta had lost their tarry color, whereas those who received only 12 grains daily gave guaiac-negative stools as soon as the stools regained their normal color.

As a check on these observations the following in vitro experiments were carried out. A solution of ferrous sulfate was made up from the tablets in therapeutic use, and the usual tests were carried out with both benzidine and guaiac reagents. Positive tests were again given by guaiac but not by benzidine. Our pathologist, Dr. F. D. Jones, suggested that the false positives with the guaiac reagent were due to tannin which gave rise to blue iron tannate. Accordingly, the benzidine reagent was used on a solution of ferrous sulfate and ferric chloride to which a small amount of tannic acid powder had been added. A characteristically blue reaction was then obtained as in the case of the guaiac reagent.

Because chlorophyll, which imparts the green color to many vegetables, is composed of pyrrole rings as is the hemoglobin molecule, it was thought that this substance might give rise to false tests for occult blood in the stools. Chlorophyll was, therefore, extracted with alcohol from various green plants and tested with both the guaiac and benzidine reagents. Both tests were negative.

CONCLUSIONS

Benzidine may give a falsely positive test for occult blood in the stools if the patient is eating considerable meat. This appears to be less likely with the guaiac test, which gives a falsely positive reaction for blood if the patient is receiving enough iron by mouth to produce tarry stools. The benzidine test is not affected by iron either in vivo or in vitro. Chlorophyll failed to give a positive reaction with either guaiac or benzidine in vitro.

*Benzidine test: Acidify a bit of feces with a few drops of glacial acetic acid and sprinkle benzidine powder mixed with sodium perborate over the resultant paste. The presence of a blue color indicates a positive reaction.

Guaiac test: Make the feces into a thick paste with water and acidify with a few drops of glacial acetic acid. To this add an equal volume of fresh alcoholic solution of gum guaiac. Mix and add an equal amount of hydrogen peroxide. A blue color indicates a positive reaction.

THE DETERMINATION OF HIPPURIC ACID IN URINE*

IDA KRAUS, PH.D., AND SOL DULKIN, B.S.
CHICAGO, ILL.

THE estimation of hippuric acid in urine after the ingestion of benzoic acid was recommended by Quick¹ as a test for liver function. According to Weichselbaum and Probst² Quick's method proved to be unsatisfactory because of an incorrect solubility factor. They modified the method by saturating the urine with sodium chloride before precipitating it with acid and in this manner they not only diminished this solubility factor, but also caused it to be more constant. Employing this modification in our own laboratory, we were unable to obtain satisfactory results. We observed that different urines behaved differently and that the addition of more acid to the filtrates occasionally brought down a further precipitate. This suggested a critical evaluation of the optimum acidity for the quantitative precipitation of hippuric acid added to urine.

In both the original and the modified methods, it was apparent that the importance of pH was not sufficiently stressed. Thus, in the original publication Quick¹ states: "Acidify (acid to Congo red) with concentrated hydrochloric acid—about one c.c., stir vigorously." Weichselbaum and Probst² (page 637) state: "Add 1.2 c.c. of approximately 10 N sulfuric acid and scratch the sides of the flask with a rod to enhance crystallization, etc." Quick³ in a later publication (page 717) states: "Concentrated hydrochloric acid is added to make urine distinctly acid to Congo red or thymol blue—usually 1 c.c. of the acid is sufficient, but it is absolutely necessary to check with an indicator paper," and adds, "an excess of acid is permissible." It would be more exact if the latter statement were to read: *an excess of acid is imperative*. The following preliminary experiment bears out this point:

To 600 c.c. of normal urine acidified with acetic acid and brought to a boil to remove coagulable material, hippuric acid was added and the solution was filtered. Into each of four beakers 150 c.c. of this urine were measured. Forty-five grams of sodium chloride were added to each, then the procedure, as directed by Weichselbaum, was continued, varying the amount of 10 N sulfuric acid as follows:

	AMOUNT OF 10 N H ₂ SO ₄ ADDED (C.C.)	AMOUNT OF HIPPURIC ACID RECOVERED	
		(GM.)	(%)
1. Acid added as directed by Quick	1.0	1.20	70.6
2. Acid added as directed by Weichselbaum with very vigorous stirring	1.2	1.45	85.3
3. Same as 1; acid added until a precipitate formed and 0.5 c.c. excess	1.5	1.67	98.3
4. Same as 3 but twice the amount of acid was added	3.0	1.70	100.0

*From the Department of Biochemistry, Cook County Hospital, Chicago.
Received for publication, March 19, 1940.

These results show that the acidity used in beakers 1 and 2, as recommended by the previous authors, although definitely acid to Congo red and to thymol blue, is insufficient to precipitate the hippuric acid quantitatively. In beaker 4, where a large excess of acid was used, the precipitate did not redissolve.

TABLE I*

BEAKER NO.	HIPPURIC ACID (GM.)	SLIGHTLY ACIDIFIED URINE (C.C.)	10 N H ₂ SO ₄ ADDED (C.C.)	RECOVERY OF HIPPURIC ACID (GM.) (DUPLICATE)		% ERROR
1	0.5	100	3.2	0.505	0.51	+3.0
2	1.0	100	2.5	0.990	0.992	-0.1
3	1.5	100	1.2	1.510	1.470	-1.3
4	2.0	100	0.8	1.980	1.950	-2.0
5	3.5	100	0.0	2.640†	2.670†	-24.0†
			2.5	0.806	0.770	-1.7

*The solubility correction given by Weichselbaum was used.

†Precipitate formed on cooling to 20° C. without the addition of acid. To mother liquor 2.5 c.c. acid was added and an additional precipitate was obtained.

The next experiment was planned to simulate clinical conditions and to show the quantitative relationship between the amount of hippuric acid in urine and the amount of inorganic acid required to precipitate it quantitatively. Obviously, the extent of impairment of liver function for which the hippuric acid test is used clinically will vary with different patients, and consequently a varied amount of hippuric acid will be excreted. Since the normal output in a four-hour specimen is given as 3 to 3.5 Gm., it is reasonable to expect that clinically an excretion of from 0.0 to 3.5 Gm. or more can be expected. A normal slightly acidified urine was used as a base and a definite amount of purified crystalline hippuric acid (m.p. 185° to 187° C.) was weighed out into a series of beakers. Tenth normal sulfuric acid was added drop by drop until no more precipitate formed, then an additional 1 c.c. of acid was added. The results are tabulated in Table I. This table shows that the amount of 10 N sulfuric acid required to precipitate hippuric acid from 100 c.c. of urine quantitatively is inversely proportional to the amount of hippuric acid present. Thus, the less hippuric acid present, as in beaker 1, the more 10 N sulfuric acid necessary to precipitate it quantitatively. About 76 per cent of the hippuric acid in beaker 5 came down with no addition of inorganic acid; to get the remaining 24 per cent, 2.5 c.c. of 10 N sulfuric acid had to be added.

The estimation of hippuric acid was made by the titrimetric method rather than the gravimetric method recommended by Quick. The gravimetric procedure is out of the question when the precipitation is carried out in saturated salt solution. To rule out the objection raised by White and associates¹ that the precipitate in addition to hippuric acid might contain unconjugated benzoic acid and glucuronic acids and thus give erroneous acidity values by the titration method, the following experiment was made: The titrated hippuric acid solution was filtered quantitatively into a volumetric flask. The beaker and filter paper pulp were washed with distilled water into the flask until no test for chloride ion was obtained, and made up to volume. An aliquot portion was analyzed for total nitrogen and compared with the calculated nitrogen from the hippuric acid titration value. The results are shown in Table II.

TABLE II

SPECIMEN NO.	HIPPURIC ACID BY TITRATION (GM.)	CALCULATED NITROGEN (MG.)	MG. OF NITROGEN BY MICRO-KJELDAHL	% ERROR
1	3.75	293	300	+2.3
2	3.14	246	257	+4.4
3	2.85	223	237	+6.2
4	3.57	280	285	+1.7
5	4.12	322	343	+6.5
6	0.52	40.6	44	+8.3

These data warrant the conclusion that no other titratable acid is precipitated along with hippuric acid, and that the titration method is reliable.

The analytical procedure now used at the Cook County Hospital is as follows: Render the urine* specimen acid to litmus with acetic acid, bring to a boil to remove coagulable material, and filter if necessary. Measure the volume, and if it is more than 150 c.c., concentrate to 150 c.c. and add 30 Gm. of solid sodium chloride per 100 c.c. of urine, i.e., 45 Gm., and heat while stirring until dissolved. Cool to room temperature by immersion in cold water, and while stirring and scratching the sides of the beaker, add drop by drop 1:1 sulfuric acid until no more precipitate forms. (It is difficult to say how much acid to add as different urines require different amounts of acid. In general, it can be said that from 2 to 5 or 6 c.c. are usually sufficient. As a precaution we test each filtrate by adding more acid to see whether precipitation is complete.) Allow to stand for fifteen minutes or more and filter through a fluted filter paper. Wash the precipitate and beaker several times with a 30 per cent solution of sodium chloride (free of sulfate ion), using a fine tip wash bottle until the last washings give negative tests for sulfate ion. Transfer the precipitate with the filter paper back to the beaker in which the precipitation was carried out. Add about 75 or 100 c.c. of distilled water and heat until the precipitate dissolves. Titrate while hot, using 0.5 N sodium hydroxide and phenolphthalein as an indicator.

It was found convenient to report results in terms of sodium benzoate.

Calculations.—

$$1 \text{ c.c. of } 0.5 \text{ N NaOH} = 1 \text{ c.c. of } 0.5 \text{ N C}_7\text{H}_5\text{O}_2\text{Na}$$

$$1 \text{ c.c. of } 0.5 \text{ N C}_7\text{H}_5\text{O}_2\text{Na} = 0.072 \text{ Gm.}$$

$$\text{Therefore, } X \text{ c.c. of } 0.5 \text{ N NaOH} \times 0.072 \text{ Gm.} = \text{grams of C}_7\text{H}_5\text{O}_2\text{Na}$$

$$\text{Solubility correction for 150 c.c. of urine} = 0.15 \text{ Gm.}$$

SUMMARY

1. The acidity used by previous investigators was insufficient for quantitative precipitation of hippuric acid.
2. The amount of inorganic acid required for a quantitative recovery of hippuric acid varies with the composition of the urine and an excess of acid is desirable.

*If specimen is bile tinted, decolorize with norit by adding 0.3 Gm. per 100 c.c. or more, depending upon the amount of bile in specimen, and boil for about a minute, then filter by suction or fluted filter paper while hot.

3. It was shown that the titration method is reliable as no other organic acids are precipitated with the hippuric acid.

4. A modified quantitative procedure is given in detail.

THE DETERMINATION OF PHENOL RED WITH THE EVELYN COLORIMETER*

HARRY SHAY, M.D., J. GERSHON-COHEN, M.D., D.Sc. (MED.), F. L. MUNRO, Ph.D.,
AND HERMAN SIPLER, B.S., PHILADELPHIA, PA.

THE use of phenol red to determine the dilution of test meals by the gastric secretion has been described by Hollander, Penner, and Saltzman.¹ Wilhelmj and Baea² modified this method by a correction for very dilute samples: mixing equal quantities of the sample and the original test meal before analysis. The purpose of this report is to record a further modification through the use of the Evelyn colorimeter³ for making the colorimetric comparisons.

To begin with, the test meal contains 1.0 mg. of phenol red per 100 c.c. instead of 2.0 mg. as used by both Hollander and Wilhelmj. When 5 c.c. of such a concentration are used as a standard, the galvanometer reading of the colorimeter is about 20. On the other hand, solutions containing as little as 0.1 mg. per 100 c.c. give a galvanometer reading of about 85. The Evelyn colorimeter thus gives a much wider working range than is feasible with the Duboseq colorimeter.

Our procedure is as follows: In a 76 by 120 mm. test tube, 5 c.c. of the sample are brought to a definite pink with finely powdered calcium oxide. Then 1 c.c. of 0.5 N sodium hydroxide and 2 c.c. of 0.3 N zinc sulfate are added and the tubes are shaken. After standing for ten minutes, the tubes are centrifuged. Five cubic centimeters of the clear supernatant liquid are placed in a colorimeter test tube and 5 c.c. of 0.5 N trisodium phosphate are added to develop the red color. The colorimeter tubes are then centrifuged for ten minutes at a speed of about 2,000 r.p.m. to throw down the zinc phosphate. The outside of the tube is wiped clean, and the reading is made using a water blank to adjust the galvanometer to 100. The filter used is Rubicon No. 565 because it transmits light of the wave length at which the alkaline form of phenol red has its maximum absorption.⁴

*From the Medical Research Laboratory, Samuel S. Fels Fund.
Received for publication, May 17, 1940.

This method eliminates one step entirely in the Hollander method, since the final reaction takes place in the colorimeter tube in which the reading is made. We have always obtained clear supernatants after centrifuging down the zinc phosphate. The volume of the precipitate is so small that its upper level remains below the light path from the colorimeter lamp.

When we first developed this technique, our studies were confined to water-glucose meals. At this time we prepared blanks by subjecting 5 c.c. samples of distilled water to our complete procedure. These blanks were used to set the galvanometer at 100 before taking our readings. We compared these settings with those obtained by using distilled water without preparation. Repeated tests showed the results to be identical, thus eliminating the need for a blank analysis. With Liebig's beef extract meals, blank analyses were made using the meal without phenol red. Although such solutions have a yellow color, with the filter of wave length 565 $m\mu$, they have a light absorption identical with that of water. We could thus eliminate the blank analyses again.

We have been using this technique for some time and find that the discrepancy between theoretical and observed values is about 2 per cent, or the equivalent of the experimental error of the Duboseq colorimeter. The use of a color filter transmitting light of a wave length which corresponds to the absorption maximum of phenol red in its alkaline form tends to eliminate interference from chromogens which were not removed by the precipitation with zinc sulfate and sodium hydroxide.

We have checked the relationship between the logarithm of the percentage light transmission and the concentration and have found that over the working range of the colorimeter it is linear. It should, therefore, be feasible to eliminate the standard and use a calibration curve. Since the stock solution of phenol red has a tendency to decrease in intensity,⁵ we believe the safer procedure is to prepare a standard from the test meal itself and thereby eliminate the possibility of error from such fading or other variation in making up the test meal. In addition to the fact that the use of the photoelectric colorimeter eliminates the obvious subjective factors involved in reading the Duboseq colorimeter, our method has the advantage of considerably shortening the time required to make the determinations.

SUMMARY

A modification of the Hollander method for determining phenol red applicable to the Evelyn colorimeter is described.

STUDIES ON THE METABOLISM OF IRON AND COPPER*

I. METHOD FOR THE DETERMINATION OF IRON AND COPPER IN BLOOD SERUM

ADOLPH SACHS, M.D., VICTOR E. LEVINE, M.D., ALFRED C. ANDERSEN, M.S., AND
AGNES SCHMIT, M.S., OMAHA, NEB.

EXPERIMENTS have been conducted in this laboratory for the past seven years to obtain data on the metabolism of iron and copper in the human body. We established the normal values for whole blood iron and whole blood copper for persons of various ages and of both sexes.¹⁻⁴ We also reported whole blood iron and copper values in the various anemias and other pathologic conditions.^{2, 5}

We found that a reciprocal relationship existed between the iron and copper content of the whole blood in anemias and allied pathologic conditions.^{2, 5} When the whole blood iron was decreased, the whole blood copper increased; and likewise when the whole blood iron increased, the whole blood copper decreased. Hypereupremia was the usual response to hypoferronemia.

Recent investigations suggest that the blood serum serves as the medium for transportation of iron in the body.⁶⁻⁸ Since copper is so closely associated with iron in the hematopoietic process, it is logical to believe that it also may be transported in the serum. Our present study of the iron and copper content of the blood serum was undertaken to gather data relative to the absorption and utilization of these two important biological elements.

The serum normally contains very small quantities of copper and non-hemoglobinous iron. Our first effort then was to establish a satisfactory method for the determination of serum iron and copper. Repeated efforts to determine the iron and copper content in the same sample of serum failed to give reliable results, hence a method was devised for the analysis of aliquot portions of serum separately for iron and copper. The chief difficulty in the latter method is that serum iron in the presence of the copper reagent, sodium diethyl-dithiocarbamate, produces a brownish color which interferes with the yellow color used for the detection of copper. Other workers also have observed this difficulty.⁹ Our attempts to overcome this interference by binding the iron with sodium pyrophosphate were successful. The binding effect of sodium pyrophosphate is demonstrated in Table I, where solutions containing known amounts of iron and copper were treated with saturated sodium pyrophosphate, ammonium hydroxide, and sodium diethyl-dithiocarbamate, respectively, and the color extracted with isoamyl alcohol. The colored alcohol layers were transferred to microcolorimeter cups and compared in the Klett colorimeter, using solution I as the standard.

*From the Departments of Medicine and Biological Chemistry, Creighton University School of Medicine, Omaha.

Received for publication, April 1, 1940.

Obviously since solutions I and VIII (Table I) checked with one another, no contamination was introduced through the use of sodium pyrophosphate. Furthermore, in solutions II, III, and IV (Table I), the experimental values agreed with the actual values, while in solutions V, VI, and VII (Table I) they did not. This fact led us to believe that the binding of serum iron is essential in the sodium diethyl-dithiocarbamate method for the determination of serum copper.

*Redistilled water, free from copper and iron, was used to prepare the sodium pyrophosphate solution.

From the results in this table we concluded that 1 c.c. of a saturated sodium pyrophosphate solution should bind completely the interfering iron present in the samples of serum used for our copper analyses, since our normal serum iron values rarely exceeded 0.020 mg. of iron per 5 c.c. of serum.

PROCEDURE

Reagents and Apparatus.—All reagents and apparatus used in these experiments were rendered free of iron and copper. Acids and water were redistilled from all-glass distillation apparatus until free from iron and copper.* The ammonium hydroxide (28 per cent) was found to be copper free, and consequently it was unnecessary to purify it.† Blanks were run frequently to check the absolute purity of the reagents used. The syringes and platinum needles used for drawing the blood samples were carefully rinsed with redistilled water before sterilization by autoclaving.

Using a sterile syringe, 37 c.c. of blood were drawn between 8:00 A.M. and 9:00 A.M. from donors who had fasted for at least twelve hours. Two 14 c.c. samples were transferred immediately to clean, dry centrifuge tubes and centrifuged. In the transfer of the blood from the syringe to the tubes, the blood was allowed to run slowly down the side of the tube without any external

*Qualitative test for iron: 5 to 10 c.c. of solution to be tested are treated with 1 c.c. of HCl, 0.1 c.c. of concentrated HNO₃, 4 c.c. of 3 N KCNS, and 2 c.c. of isoamyl alcohol. If the alcohol layer is colorless, the test solution is free from iron.

†Qualitative test for copper: 5 to 10 c.c. of solution to be tested are treated with 0.5 c.c. of 28 per cent NH₄OH, 2 c.c. of sodium diethyl-dithiocarbamate, and 2 c.c. of isoamyl alcohol. If the alcohol layer is colorless, the test solution is free from copper.

†The ammonium hydroxide was obtained from the Mallinckrodt Chemical Co.

pressure on the plunger. Likewise when the blood was withdrawn from the veins, no suction was exerted on the plunger. This precaution must be taken in order to avoid hemolysis. The remaining blood was transferred to a large test tube containing 15 mg. of sodium oxalate and was used subsequently for the determination of hemoglobin and of whole blood iron and copper, cell volume, and for the making of red and white blood cell counts. The samples from which the serum was obtained were centrifugated at 1,500 r.p.m. for one and one-half to two hours. After centrifugation the serum was carefully removed from the cells and tested for hemolysis.

Testing the Serum for Hemolysis.—Using a 5 c.c. Ostwald-Folin pipette, a sample of serum slightly in excess of 5 c.c. was withdrawn, and the serum allowed to flow into a dry receptacle until the 5 c.c. mark was reached. This serum was employed for the benzidine test. The remaining 5 c.c. were transferred quantitatively to a vitreosil dish.

Benzidine Test for Hemolysis.—To a clean 15 c.c. test tube exactly two drops (equivalent to 0.2 c.c.) of the blood serum for the benzidine test, 1 c.c. of 1 per cent benzidine dihydrochloride* solution, and 1 c.c. of 3 per cent hydrogen peroxide were added. The 3 per cent hydrogen peroxide was prepared from superoxol (30 per cent H_2O_2) by dilution. If a blue color appeared, the benzidine test was positive, indicating the presence of hemoglobin. A serum sample giving a positive benzidine test was not used for serum iron determinations. It was used for serum copper determinations, however, if only a slight blue color was obtained in the benzidine test. Our results have indicated that traces of hemoglobin do not affect the accuracy of serum copper analyses.

We have found this benzidine test capable of detecting hemoglobin in blood which has been diluted 1:100,000; that is, 1 c.c. of this diluted sample containing 1.14 μg of hemoglobin, or 0.0038 μg of hemoglobin iron, gave a positive benzidine reaction. The hemoglobin content of the blood sample was calculated from the iron content of 5 c.c. of whole blood, as determined by the dry ash method. This test was performed on each freshly prepared solution of benzidine dihydrochloride to insure the constant sensitivity of our benzidine test.

Because this test is capable of detecting 0.0038 μg of hemoglobin iron, a negative benzidine reaction in 0.2 c.c. of serum would indicate that there is no more than 1.9 μg of hemoglobin iron in 100 c.c. of serum. This amount of iron falls well within the limits of experimental error, and, therefore, may be considered negligible.

SERUM IRON DETERMINATION

Five cubic centimeters of benzidine negative serum were transferred to a vitreosil dish and evaporated to dryness on the hot plate, with constant stirring to prevent spattering. The contents were covered and ashed for eight hours in an electric furnace. One cubic centimeter of concentrated nitric acid was then added, and the contents were evaporated to dryness on the hot plate. If ashing was incomplete, it was finished at this stage by heating gently over an open flame until all traces of carbon disappeared. Two and one-half cubic centimeters of 6 N hydrochloric acid were added, and the solution was warmed slightly to dissolve the ash completely. The contents were transferred quantitatively to a

*The crystalline benzidine dihydrochloride was obtained from Eastman Kodak Co. A 1 per cent solution of the salt was stable for at least a month.

50 c.c. glass-stoppered cylinder, the dish was washed carefully with redistilled water containing 0.5 c.c. of 6 N hydrochloric acid, and the wash was transferred to the cylinder.

The standard was prepared as follows: Using a 1 c.c. Ostwald-Folin pipette and a standard iron solution containing 10 μg of iron per cubic centimeter, 1 c.c. of the iron solution (equivalent to 10 μg of iron) was transferred to a 50 c.c. glass-stoppered cylinder, and 3 c.c. of 6 N hydrochloric acid were added.

To both standard and unknown 0.1 c.c. of concentrated nitric acid was added, and the containers were rotated gently to insure thorough mixing. Exactly 4 c.c. of 3 N potassium thiocyanate and 4 c.c. of isoamyl alcohol were added. The cylinders were stoppered and shaken for one to two minutes and then allowed to stand until the alcohol layer separated from the aqueous solution.

Using a small pipette, the colored alcohol layer was transferred to a dry acid-washed filter paper, 1 inch in diameter, and filtered into a microcolorimeter cup. Comparison in the colorimeter was made as soon as possible.

SERUM COPPER DETERMINATION

Five cubic centimeters of serum were transferred to a vitreosil dish and evaporated to dryness, with constant stirring to prevent spattering. The contents were covered and ashed for eight hours in an electric furnace. One cubic centimeter of concentrated nitric acid was added, and the contents were evaporated to dryness on the hot plate. To insure complete ashing the residue was heated gently over an open flame until all traces of carbon disappeared. The ash was then dissolved in 2.5 c.c. of 6 N hydrochloric acid, warming slightly to dissolve it completely, and transferred quantitatively to a 50 c.c. glass-stoppered cylinder. The dish was finally washed with redistilled water containing 0.5 c.c. of 6 N hydrochloric acid, and the washings were transferred directly to the cylinder.

A copper standard was prepared as follows: Using a 1 c.c. Ostwald-Folin pipette and a standard copper solution containing 10 μg of copper per cubic centimeter, 1 c.c. of the copper solution was transferred to a 50 c.c. glass-stoppered cylinder, and 3.0 c.c. of 6 N hydrochloric acid were added.

Using redistilled water, both standard and unknown were made up to a volume of approximately 35 c.c. To both standard and unknown 2 c.c. of concentrated ammonium hydroxide were added. The solutions were cooled, and 1 c.c. of a saturated solution of pyrophosphate, 2 c.c. of an aqueous solution of 0.5 per cent sodium diethyl-dithiocarbamate reagent, and 4 c.c. of isoamyl alcohol were added. The contents were shaken for one to two minutes and then allowed to stand until the alcohol layer separated from the aqueous solution. Using a small pipette, the colored alcohol layer was transferred to a dry acid washed filter paper as for serum iron, and filtered into a microcolorimeter cup. Comparison was made in the colorimeter.

Some of the serum iron and copper values which we have obtained using the method outlined are listed in Table II. These samples were obtained from normal male college students, 20 to 30 years old.

Average			15.25	0.150	0.105	51.30	0.125	1.06	

*The hemoglobin values were calculated from the whole blood iron values, using the Butterfield factor:

$$\text{Hemoglobin, Gm. in 100 c.c. of blood} = \frac{\text{Milligrams of iron in 100 c.c. of blood}}{3.35}$$

$$\text{†Iron color index} = \frac{\text{Milligrams of iron in 100 c.c. of blood}}{\text{First two figures of red blood cell count}}$$

COMMENT

On the whole, the serum iron values which we have obtained using the method outlined (0.103 to 0.258 mg. per 100 c.c. of serum) fall within the range reported by other investigators who used different methods. Moore and his collaborators, from an analysis of fifteen male subjects, reported a range of 0.094 to 0.174 mg. per 100 c.c.⁶ Walker¹⁰ reported a range of 0.040 to 0.230 mg. per 100 c.c. from a series of twelve medical students. Fowweather¹¹ obtained a range of 0.095 to 0.180 mg. per 100 c.c. Other workers, not specifying the sex studied, reported such values as the following for 100 c.c. of serum: Locke, Main, and Rosbash, 0.083 to 0.115 mg.; Warburg and Krebs,¹² 0.067 to 0.116 mg.; Barkan,¹³ 0.056 to 0.140 mg.; and Langer,¹⁴ 0.050 to 0.180 mg.

We have observed in an occasional case a marked deviation from the general range of values reported. This suggests the possibility that the absorptive state of the individual and the iron content of his diet for a period of time preceding the analysis are possible factors affecting serum iron concentrations.

The serum copper values we have obtained (0.082 to 0.132 mg. per 100 c.c. of serum) are slightly higher than those of Locke, Main, and Rosbash,⁹ who reported a range of 0.073 to 0.087 mg. per 100 c.c. for eight cases, and of Warburg and Krebs,¹² who stated 0.082 mg. per 100 c.c. as their average value for ten adults.

We are continuing our determinations so as to establish a larger series of normals that may give us a more accurate range of normal values which we intend to publish at a later date.

SUMMARY

1. A relatively simple dry ash method has been described for the determination of iron and copper in blood serum. Aliquot samples of serum were evaporated to dryness and ashed in an electric furnace for eight hours; the ash was

treated with nitric acid, dissolved in dilute hydrochloric acid, and transferred to glass-stoppered cylinders. The solution in one cylinder was then analyzed for serum iron, the other for serum copper. For iron analysis the solution was treated with nitric acid, 3 N potassium thiocyanate solution, the color was extracted with isoamyl alcohol, and the unknown was compared with a standard in a colorimeter. For copper analysis the solution was treated with ammonium hydroxide, sodium pyrophosphate, and sodium diethyl-dithiocarbamate. The color was extracted with isoamyl alcohol and the unknown was compared with a standard in the colorimeter.

2. Using this method, values for the iron and copper content of the serum of ten male adults are reported. The serum iron values range from 0.103 to 0.258 mg., giving an average of 0.150 mg. per 100 c.c. of serum. The serum copper values range from 0.084 to 0.132 mg., yielding an average of 0.105 mg. per 100 c.c. of serum.

MEDICAL ILLUSTRATION

AN INTRODUCTION TO ILLUSTRATION

CARL DAME CLARKE, PH.D., BALTIMORE, MD.

WITH ILLUSTRATIONS BY ELIZABETH S. CONE AND CARL DAME CLARKE

IN ESTABLISHING the Department of Medical Illustration in this JOURNAL I feel that an introduction to illustration is in order. This subject has been discussed somewhat at length in previous articles and books.¹⁻⁴ At best this introduction is only a short summary to call to the reader's attention the different types of illustration and how they may be used.

For the purpose of portrayal the scientist has at his disposal three mediums of illustration. The first of these is photography, the second is drawing or painting, and the third is modeling. In this latter medium, molds and casts of the actual subject are employed more than sculptured models. For the purposes of medicine photography is used more than drawing, and drawing is used more than modeling. It is common for the scientist to overlook the possibilities of one medium of illustration in his enthusiasm for another.

There are some cases in which the photograph will serve as a better illustration than the drawing, and other cases in which the drawing is indispensable. The wax or rubber model serves best in the small classroom where it can be used during a didactic lecture. *The medium of illustration to be chosen depends entirely on the subject to be illustrated and the purpose for which the illustration is to be used.* The photograph is the cheaper method and takes less time to produce. Naturally, it is the most popular method of illustration. There are cases in which it is absolutely impossible for the photograph to show to good advantage in comparison with the drawing. There are also instances in which the making of a drawing would be an unnecessary expense and a waste of time when the photograph would be sufficient.

Examples of cases where the ordinary photograph is suitable are as follows: skin lesions in which color is of little importance; deformities of any part of the body that manifest themselves on the outer surfaces; pathologic specimens void of color, as after fixation in formalin; apparatus of various types, such as chemical, surgical, and medical. In many cases pen-and-ink diagrammatic line drawings of apparatus show to better advantage the operation of such equipment.

There are cases in which the best photograph is worthless in comparison with the drawing made by the finished artist. It is not only hazardous, but practically impossible, to obtain a photograph through the small incision that is made

to gain access to the abdominal and thoracic viscera. Even the most proficient photographer, using the best equipment, is likely to fail or refuse to try. Without doubt the mechanics of surgery are best illustrated through the medium of draftsmanship. Even the simple pen-and-ink diagram is often superior to the most perfected photograph in presenting a surgical procedure for mental absorption.

In many cases drawings are superior not only because of the inaccessibility of the field, but also because important structures are often covered by blood, mucus, fascia, fat, and other unimportant parts that prevent a clear view to the lens of the camera. The artist can eliminate these obstructions from his drawing, but it is generally impossible for the photographer to do so in his photograph. Of course, photographs can be retouched, but when any great amount of retouching is done the photograph becomes more of an art job than a photograph. To this end it would have been better for the artist to have made the entire illustration.

In comparing the drawing and the photograph made through the microscope, it often becomes a matter of personal taste on the part of the physician as to his preference. I am of the opinion that the average physician is more accustomed to poor photomicrographs than he is to good ones. Not all physicians are fortunate enough to have at their disposal trained medical artists and photographers. In fact, the making of medical pictures is often left to artists and photographers doing the usual run of commercial work. Few, if any, commercial photographers have the equipment for making photomicrographs, and since this is a highly developed and specialized field of photography, few of them understand how to obtain the best results. Therefore, photography of this type is left to the pathologist or laboratory worker, who may be very proficient in his own field but a poor photographer. He may consider his results good until a comparison with truly excellent photographs is made.^{6, 7}

The photomicrograph of a few years ago was a poor excuse for a good drawing made at the same time of the same subject. With the continued development and use of panchromatic photographic plates, color filters, apochromatic lenses, and perfected photomicrographic apparatus, the drawing of the microscopic subject is beginning to recede into the background. Photomicrographs of any microscopic section can be made through any known and used power of lenses. In other words, low-power pictures covering the entire section can be produced as well as the pictures made through the oil-immersion lens. Any degree of magnification between these two can be successfully obtained and the section photographed at that specified power. Magnifications between those given by combinations of specified oculars and objectives may be obtained by extending the bellows of the photomicrographic camera.

It is possible for the artist to accentuate any part of the cell structure as well as "hold back" the insignificant parts in a microscopic slide. The photographer can do the same thing by the use of the proper color filter or filters, with the correct plate and slight variations in exposure, and development of the negative and positive. Small sections of a negative may be accentu-

ated by the use of a dye on other parts of the negative to hold them back during the printing, or by the use of tissue paper beneath the negative in the printer. It stands to reason that the photograph is a truer representation of the original. However, in high-power work detail and depth in a cell are often difficult to obtain by photography. The artist can improve on some photomicrographs because he can make a composite picture of what comes in and out of view as he focuses his microscope up and down. A high-power photomicrograph may be good as far as the photographic technique is concerned, but a drawing of the same subject can be superior because of the ability of the eye and hand to record on paper in a single picture the various depths of a microscopic section.

Fig. 1.—A typical half-tone drawing for the illustration of the mechanics of surgery.

It is possible to combine drawing with photography to produce a drawing or a picture composed of both drawing and photography. The silver print or photochemical method of combining drawing and photography is a procedure that can be applied to the making of any type of drawing. However, it is more suitable for pen-and-ink illustrations. It can be used for the wash, water color oil color, tempera, and even pencil dust techniques. This subject has already been discussed fully⁸ and will not be dealt with in this introduction.

Natural color photographs can be made and used for lantern slides or publication. These pictures in color are made on glass or celluloid film and are often exceptionally well done. As a rule, the natural color photograph compares favorably with the best color drawings used in scientific publications. However, the artist has at his disposal many colors from which he may make hundreds of combinations. The natural color photograph is generally composed of three

Fig. 2.—Sometimes a simple pen-and-ink semidiagrammatic sketch serves best as a drawn illustration.

colors; therefore all colors must be those that are originally in the emulsion or the combinations that can be obtained by optically mixing these colors. A good color photographer will invariably produce a better color picture than a poor artist and, in turn, a good artist will produce a better color picture than a poor photographer.

The artist may be able to color or tint photographs, but the drawing or painting by the skilled artist without photographic aid is usually superior. Photographs to be colored or tinted as medical illustrations should be made first in sepia tone. This is necessary as the black undertone has a tendency to "kill" or destroy the brilliancy and strength of warm colors such as reds and yellows. These colors are used in painting or glazing over the photograph.⁹

One of the important factors to be considered before having full-tone colored pictures made, whether colored photographs or paintings, is the expense of reproduction. This expense is augmented by the necessity of making numerous photoengraved cuts, one of each color, and the added processes of printing. Many medical journals require the author, or the institution with which he may be affiliated, to bear the cost of color reproductions. However, the cost of full-tone color pictures is greatly reduced by using flat color only. Structures such as veins, nerves, and arteries, can be accentuated by the use of flat color over black-and-white half tones or line drawings. The color illustrations in the *Hand Atlas of Human Anatomy* by Spalteholz are examples of the use of flat color in photoengraving. The average magazine cover is generally reproduced in full tone.

It is my assumption that better reproductions in black and white are obtained from photographs or drawings that are themselves in black and white rather than in color. For this reason, if the picture is not to be reproduced in color, the artist or photographer should make the original in black and white.¹⁰

Practically all lantern slides are made by the photographic process, regardless of what the original may be. One exception to this rule is when the diagram or sketch is drawn directly on a prepared glass of lantern slide size; another is the process of typewriting through carbon paper placed next to a piece of cellophane or celluloid. This latter method gives a carbon impression on the cellophane, which is then mounted between two lantern slide cover glasses for projection.¹¹

The same problems, as well as many others that arise in still photography, apply to motion picture photography. The scientist should write out a scenario before proceeding. This is of considerable importance in making excellent professional motion pictures. Generally a picture is taken of a surgical operation or similar procedure. After the film is developed, titles are inserted or the film is scored with sound. Few scientific films tell their stories as clearly or coherently as a logical sequence of events.¹²

The scientist should bear in mind that the preparation of a motion picture is comparable to the preparation of an article for publication. An outline or scenario is made, the material is gathered and then photographed, the negative is edited, and finally the negative is titled or scored with sound and printed. This produces a continuous film without patches which cause noise and shaking on the screen. Most persons prefer to edit a positive print, then make the negative correspond to the positive. However, if the editing is done on the negative, the expense of an additional positive is eliminated. A scientific subject that is worth recording is usually worth making into both the negative and the positive rather than reversing the negative into the positive, which is the

Fig. 3.—In the past most microscopic subjects were drawn, as is shown in this illustration.

Fig. 4.—The above photomicrograph of a case of tuberculosis of the cervix may be used for comparing with the drawn microscopic picture in Fig. 3.

general rule. It is slightly more difficult to follow the action on the negative than on the positive. The difference in price between Kodachrome or color film and panchromatic film warrants the use of color film entirely for most scientific subjects. This positive color film should be edited, titled, or scored with sound, and immediately duplicated before it has been run long enough to receive annoying scratches.

Animated drawings are playing an important part in scientific illustration. Their production is so highly technical that it becomes a specialized field within itself. The artist who intends to make acceptable animated drawings should, in addition to his knowledge of art, understand the fundamentals of photography, especially motion picture photography. These fundamentals embrace lens action, such as focusing, focal length, and speed of lenses, as well as exposure; the mechanics of the time lapse motion picture camera; and, finally, the technique of the processing room, for it is here that many interesting and necessary animated effects are produced with chemicals and the printing machine.

Fig. 5.—The three-dimensional wax cast serves best for museum purposes and for study in the small classroom.

These, of course, apply only to the artist who does his own camera work. However, it is advantageous to learn the fundamentals of the entire process. Photography and drawing are so interdependent for the animation worker that a description of one is inadequate without a description of the other. The motion picture, when properly conceived, photographed, and edited, becomes man's most powerful tool for the dissemination of knowledge. Animation provides a means of obtaining motion pictures which cannot be produced by ordinary cinematography. In other words, animated drawings accomplish the same purpose for the motion picture that an ordinary drawing accomplishes for the textbook. It seems evident that animated drawings will play an even greater part in the dissemination of scientific knowledge than they do at present. This is indeed a fascinating branch of scientific illustration and will not only be in-

teresting to the artist and photographer, but will also tax his ingenuity and imagination in developing new processes and equipment.¹³

Wax or plaster casts can be made of skin lesions, deformities, and abnormal growths and depressions of the body. These molds and casts are made by first applying liquid plaster of Paris or an agar composition to the properly prepared surface. When these materials have set and are removed, they constitute the mold, which in turn is filled with plaster, wax, celluloid, or rubber. The mold is removed after the hardening of the positive material, thereby producing an exact impression which shows such details as the pores of the skin, provided the work has been done properly.

The agar composition is pliable enough to permit free removal of the mold from the anatomic part in cases where there is a degree of undercutting. The agar composition¹⁴ is more suitable for use on the living body or on fresh structures after removal from the body. For the inanimate object composed of plaster or wax the rubber mold serves best. The simplest rubber molds are made from prevulcanized latex combined with cellulocotton.

By the use of molds and casts lifelike reproductions can be made of extremities, skin conditions, or any part of the abdominal or thoracic viscera after its removal from the body. These casts can be colored to represent the originals and often have been mistaken for the actual organ or part.

Cut or destroyed parts of specimens can be reconstructed before casting. If the worker is clever, he can model or sculpt the entire subject in clay, wax, or plasteline. From his original work a rubber or plaster piece mold can be made to reproduce a number of casts in colored wax or plaster.⁴

Casts are considered to be the best representation of the original but are more cumbersome to handle in exhibiting than the photograph or drawing. Photographs and lantern slides can be made from them for reproduction or projection. Wax or plaster casts serve best as museum pieces. They can also be used for student instruction in small groups.

The possibilities of moulage making are unlimited. Its value to the human race warrants further study and rapid propagation. As an example, consideration should be given to the crude, artificial anatomic appliances which are attached to the body in the vain hope that they will make the unfortunate wearer happier, more presentable to society, and better equipped to cope with the ever-mounting competition of commercial, social, and economic existence. It is indeed deplorable that such prostheses have not been perfected to a degree that would produce realistic, natural, and comfortable appliances of practical use. The present-day artificial limbs are examples of prostheses that lack realism. False teeth have been perfected to a greater extent. There is little reason why other artificial parts should not be developed to the same degree.^{4, 14, 15}

An effort should be made to establish a technique in its most simple form. When this is accomplished, other incomplete fields may be conquered and additional knowledge may be gained. In fact, new ideas will develop and encourage the worker to return to the original problem in order to raise it one step nearer the unattainable peak of perfection. The goal is unlimited but the zest of trying is worth the effort.

In conclusion, it may be repeated that the subject to be depicted and the purpose for which the illustration or reproduction is to be used determine the medium through which it should be produced. It will be well worth the physician's time to discuss this matter fully with the artist and the photographer before he blindly orders a paper to be illustrated. It is hoped that such a discussion will improve medical illustrations and their worth in conveying ideas from one person to another.

Erratum

On page 554 of the December number of the JOURNAL in the article by Vera B. Dolgopel, M.D., and Helen Y. Markus, M.T., entitled "Rapid Diagnostic Method for Testing the Virulence of Corynebacteria," the second sentence under *Virulence Test* should read:

"A similar amount was injected *intracutaneously* into another guinea pig which was used for the same number of control tests, and 500 units of diphtheria antitoxin was given *intraperitoneally*."

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

SYPHILIS, Latent, A Serologic Verification Test in the Diagnosis of, Kahn, R. L. Arch. Dermat. & Syph. 41: 817, 1940.

A serologic test is presented in this article which should help to detect false positive reactions obtained in the serodiagnosis of syphilis. The test is based on experimental studies which indicate that sera of nonsyphilitic persons which give positive reactions possess characteristics that can be differentiated from those possessed by sera of syphilitic persons. The technique of the test is similar to that of the standard Kahn test, except that it is carried out at 37° C. and at 1° C. The technique is applicable in questionable cases of syphilis in which sera give doubtful or positive reactions with a diagnostic test.

The method follows:

In the performance of the verification test, a thorough knowledge of the Kahn test is necessary. In a broad sense, the verification technique consists in performing Kahn tests at 37°, 21°, and 1° C. Since such tests are routinely carried out at approximately 21° C., the basic differential temperatures are 37° and 1° C.

In carrying out the technique at 37° C., the reagents as well as the glassware must be properly warmed, and the reagents must be mixed under warm conditions. 1. Kahn racks and tubes are warmed by placing them in a 37° C. water bath fifteen minutes before performing the test. The pipettes are kept in a 37° C. incubator. 2. Standard Kahn antigen is mixed at room temperature in the usual manner with saline solution according to the titer. The antigen suspension is then transferred to a Kahn tube, stoppered and placed in the water bath for fifteen minutes. 3. The serum is heated for thirty minutes at 56° C. (132.8° F.) and is then placed in the 37° C. water bath for fifteen minutes before being pipetted into the antigen suspension. 4. The amounts of antigen suspension (0.05, 0.025, and 0.0125 c.c.) are deposited at the bottom of the Kahn tubes, followed by the serum (in 0.15 c.c. quantities), and the mixture is shaken for ten seconds without removing the rack from the water bath. The racks remain in the bath from five to ten minutes and are then shaken for three minutes under standard conditions. 5. Physiologic solution of sodium chloride, kept in a 37° C. water bath, is then added to each tube in the usual amounts (1, 0.5, and 0.5 c.c.); the tubes are agitated sufficiently to assure proper mixing, and the results are read immediately. 6. A microscope mirror or a slit lamp is used in the reading of results. The precipitation readings in each tube are recorded in the usual manner.

The technique at 1° C. requires an ice-water bath, which can be easily improvised with chopped ice. A square, flat-bottomed pan, 6 inches (15 cm.) or more deep and large enough to hold several racks, will be found adequate. Every step in the technique as carried out in the 37° C. water bath is applicable to that in the 1° C. water bath. It is important not only to bring the temperature of the serum and antigen suspension to 1° C. but also to see to it that the serum is added to the antigen suspension and mixed at this temperature. Tests performed at 1° C. may require special care in reading owing to the film of moisture that condenses on the outside of the tubes. This film may be wiped off with a cloth and the results read as previously indicated.

In the experiments described in this article the three-minute shaking of the tubes was carried out at room temperature. In experiments to be undertaken it is planned to determine the effects of shaking at 37° C. and at 1° C.

It is suggested that no more than ten tests be carried out at any one time, either at warm or at cold temperatures.

In view of the fact that the basic value of the test under consideration lies in the difference in the precipitation results at 37° and 1° C., it is evident that technical steps which do not adhere strictly to these two temperatures will neutralize the value of the results.

GLUCOSE, Renal Threshold for; Normal and in Diabetes, Lawrence, R. D. Brit. M. J. May 11, 1940.

The study of the renal threshold in diabetic and normal persons with healthy renal function shows frequent upward and downward deviations from the accepted "normal" figure of some 170 mg. per 100 c.c.

The conception of a "normal" threshold is false. There is an average renal threshold, just as there is an average blood pressure, and the many deviations from it should be looked upon as physiologic—a matter of individual idiosyncrasy, and of no pathologic significance.

High and low thresholds are frequent and usually persist at the same level throughout life. A few factors outlined above affect the threshold temporarily or even permanently.

The stigma of something abnormal (and hence pathologic) that has been imputed to a high or low renal threshold should be removed.

BRUCELLA: The Presence of a Capsule on Brucella Cells, Huddleson, I. F. J. Am. Vet. M. A. 96: 708, 1940.

Capsules have been demonstrated by the method following:

A dilute suspension of Brucella cells is prepared in physiologic salt solution or distilled water. A small drop of the suspension is placed near one end of a clean microscope slide, and drawn across the slide by placing the end edge of another slide at one angle in front of the drop. The film of bacteria is dried in the air. A small drop of Keuffel and Esser India drawing ink No. 3000 is placed back of the beginning of the previous smear and drawn over it with the end edge of another slide. The ink smear is allowed to dry in the air. The smear is now treated with methyl alcohol containing 0.2 per cent glacial acetic acid for five seconds and again air-dried. The slide, film up, is placed on a rack and stained five minutes with aniline crystal violet previously diluted 1:1 with distilled water. The excess stain is now washed off with distilled water and the smear is air-dried.

On examining the smear under the microscope (oil-immersion objective, 10 or 12 × ocular), it is necessary to move the slide to an area where the ink smear is not too dense in order to view the encapsulated bacteria in their normal size. The soma appears as a deep purple coccus or rod inside the capsular material, which stains light pink or purple. If the smear is fixed for five seconds with 5 per cent acetic acid prior to staining, the capsular material does not stain but appears as a light halo around the soma or bacterial body. The size of the capsule depends upon the size of the soma. The size varies from 1.5 to 2.5 microns.

The capsule appears larger in recently isolated cultures and in those that have grown on culture media for not longer than seventy-two hours.

Cultures that have become completely dissociated or rough do not show a capsule.

WEIL'S DISEASE in Hawaii, Tokuyama, S. J. A. M. A. 114: 2195, 1940.

Twelve cases of hemorrhagic spirochetel jaundice were observed in Hawaii, the diagnosis being confirmed clinically in two cases and bacteriologically in nine cases. The disease was proved to be identical with that occurring in Japan by both clinical and bacteriologic criteria.

Nine of the twelve patients were inoculated with the *Leptospira icterohemorrhagiae* serum of Inada and Ido; seven of the inoculated patients were cured and two died. Death was due to the delay of the serum injection.

Three of the patients did not receive the serum; of these, two died but one recovered.

DARKFIELD, A New Technic for, Sizemore, T. *Am. J. M. Technol.* 6: 120, 1940.

The ulcer or lesion to be examined is cleansed carefully with sterile normal saline or Ringer's solution, removing all debris and pus. The ulcer is then dried by the application of ether. A sufficient amount of serum for examination may be obtained by exerting general pressure upon the sides of the ulcer or lesion. Place the top of an ordinary blood coagulation pipette to the serum and tilt until enough of the serum is drawn into the pipette. Transfer to a clean slide using a small rubber bulb to expel the serum. Place a cover glass over the serum immediately and compress it slightly. Mount as usual in cedarwood oil.

URINE, The Formation of, Edwards, J. G. *Arch. Int. Med.* 65: 800, 1940.

In the kidneys of all classes of vertebrates the proximal convolution is primarily secretory and is the only part of the tubule invariably present. The structure and functions of the tubule, when viewed phylogenetically and when studied in health and in disease, would seem to have an importance much greater than is at present demonstrable in detail. Comparative renal studies dealing with the aglomerular kidney, and inaugurated by the author in this connection, have been productive of much interest in secretion by the tubule. It is hoped that eventually the actual role of the tubule in urine formation will be established.

The phylogenic development of the corpuscle as the site of filtration is related to that of the distal convolution as the site of resorption. Filtrable substances in the plasma are excreted by the corpuscle regardless of possible depletion of body fluids and consequent damage to the tissues. The distal convolution, aided in birds and mammals by the thin segment and the ascending limb of the medullary loop, performs by resorption the function of salvage. The hypotonic urine of cold-blooded animals indicates that there has been resorption of relatively more of certain solutes than of water; the hypertonic urine of warm-blooded animals indicates the opposite.

A filtrable fraction of plasma is excreted into the lumen of the tubule by the corpuscle and by the cells of the proximal convolution. Minimal amounts of protein are present in this fraction because the passage of larger amounts is prevented by the epithelial wall adjacent to the glomerular and peritubular capillaries. Many factors so affect filtration by the corpuscle, however, that albuminuria readily develops. The extreme sensitiveness of this structure to such normal or pathologic changes as those which occur in the chemical composition of plasma or in blood pressure flow or volume is responsible for confusing variations and dubious interpretations of its activity.

Diuretics are initially and chiefly effective by their direct or indirect action on one or more of the components of the cardiovascular system. Neither diuretic urine nor the subnormally concentrated urines formed after renal injury should be regarded as necessarily indicating impairment of the resorptive power of the tubule. Urines of low specific gravity may be variously formed as a result of excessive filtration, of decreased resorption of water, or of increased resorption of solutes.

It is not yet established that the formation of urine is primarily the result of filtration and resorption or that resorption is the chief function of the tubule as a whole.

SHOCK: Circulatory Failure of Capillary Origin, Moon, V. H. *J. A. M. A.* 114: 1312, 1940.

Circulatory failure of capillary origin produces a clinical syndrome which is highly characteristic. This is accompanied by an equally characteristic group of abnormal physiologic and biochemical features. These constitute the clinical syndrome of shock.

The gross and microscopic changes seen post mortem are equally significant. These consist of evidences of capillary damage, such as dilatation, stasis, petechial hemorrhages, edema, and effusions, present in extensive visceral areas. These features are etiologically related to the mechanism by which circulatory deficiency of capillary origin develops.

Hemoconcentration is a highly valuable clinical sign indicating the early stages of this condition. It occurs before other signs of circulatory deficiency are manifest.

The mechanism of this type of circulatory failure includes the reciprocal effects of two major factors—capillary atony and tissue anoxia. Either of these factors will presently cause the development of the other. This reciprocal action gives the circulatory deficiency a self-perpetuating quality which tends toward an irreversible condition.

Few conditions of disease present a more characteristic group of clinical features, physiologic abnormalities, and morphologic visceral changes. This syndrome, if caused by a single etiologic agent, would constitute an entity among diseases. But the origin of this syndrome is highly diversified. It may originate from the numerous and varied agents and conditions which may injure directly the capillary endothelium, from loss of blood and/or fluid sufficient to produce systemic anoxia, from agents or conditions which reduce the volume flow of blood below physiologic limits, from asphyxia of external or internal origin, or from various combinations of the conditions mentioned.

Efforts to combat this type of circulatory deficiency will be directed toward the recognition and removal of the cause and toward interrupting the operation of the vicious circle. If the former cannot be accomplished, the latter will be ineffective.

Until some agent is found which will prevent or relieve capillary atony, efforts to interrupt the cycle should be directed toward the restoration of blood volume and toward relieving the anoxia. The tendency to progress toward irreversibility requires early recognition and action. Hemoconcentration is recommended for recognizing the early stages of circulatory deficiency of this type.

URINE: Control of Urinary Reaction, Bridges, M. A., and Mattice, M. R. *Am. J. M. Sc.* 200: 84, 1940.

The urinary pH cannot be consistently changed at will without regard for its natural trend.

The acidifying or alkalinizing effect of test substances cannot be judged solely by the urinary pH observed. Comparison with the fundamental or natural curve is necessary.

The natural acid-base curve can be distorted by dietary factors with variable ease in different subjects.

The determination of urinary pH following meals is of no practical clinical value.

It has not been possible by dietary measures to produce continuously alkaline urine.

Temporary elevation of urinary pH is most readily secured with cantaloupe.

The easiest means of maintaining acid urine in the normal individual is the substitution of cranberry juice for water as such in the diet.

The effective action of acidifying drugs is conditioned by the amount of water simultaneously claiming excretion.

Although concentration of urine is regularly associated with increasing acidity and dilution with increasing alkalinity, the normal kidney can excrete a highly acid dilute urine and a definitely alkaline concentrated urine. The elimination of water is not constant throughout the day, thus influencing the urinary pH.

Emotional and mental states demonstrably affect urinary pH.

PNEUMONIA, Sabin Agglutination Test as a Control of the Sulfapyridine Treatment of
Fox, W. W., Rosi, R., and Winters, W. L. *Am. J. M. Sc.* 200: 78, 1940.

Fifty adult patients with pneumococcal lobar pneumonia treated with sulfapyridine were studied to determine the time at which active immunity first appeared.

All patients with proved type-specific pneumococcal pneumonia developed strongly positive agglutinins at some time in the course of their illness.

Strong type-specific agglutination occurred in the uncomplicated cases on an average of 8.3 days after the onset of the disease; in complicated cases it occurred on an average of 12.5 days.

When active immunity did not appear early in the second week of the disease, complications or delay in resolution frequently occurred.

Persistence of a strongly positive agglutination for the homologous type pneumococcus was a favorable prognostic sign.

Occasionally, empyema developed after a strongly positive agglutination appeared. All such cases, however, had bacteriemia on admission and in some cases this persisted for twenty-four hours or longer after sulfapyridine therapy was begun.

The authors believe that recovery from pneumonia in patients treated with sulfapyridine requires: (1) adequate blood sulfapyridine concentration, (2) maintained leucocytosis, and (3) development of active immunity by the patient in response to his infection.

In uncomplicated pneumococcal pneumonias a safe rule appears to be to continue sulfapyridine therapy at a dosage which will produce a blood level above 4 mg. per 100 c.c. until a strongly positive microscopic agglutination test is obtained with the patient's serum against pneumococci of the type with which he is infected. In complicated pneumococcal pneumonias sulfapyridine should be continued, if possible, until the temperature and pulse have returned to normal, even though strongly positive agglutination has occurred prior to that time.

TRICHINOSIS, Incidence of, in 300 Autopsies at the University Hospital, Ann Arbor, Michigan, Catron, Lloyd. *Am. J. Hyg.* 1: Sec. C, 1940.

Forty-four instances of trichinosis (14.7 per cent), all unrecognized clinically, were found by examination of diaphragms obtained from 300 autopsies at the University of Michigan Hospital. All the infestations were shown by digestion of samples of 50 Gm. or less; three were found by examination of a single microscopic section from each diaphragm; and eight were found in the 270 cases in which 1 Gm. of diaphragm was examined microscopically. The digestion method, although demonstrating every infestation, proved inadequate to show the total number present when the larvae were dead and calcified.

TISSUE: Pathologic Changes Observed in Human Tissues Subjected to Subcritical Temperatures, Smith, L. W. *Arch. Path.* 30: 424, 1940.

In this paper a brief summary of the pathologic studies in a series of some 60 cases in which patients with cancer were subjected to local or general reductions of temperature and in which autopsies were made is presented. The studies are divided into three major groups: first, those relating to the normal body tissues; second, those relating to tumor tissue subjected locally to temperatures of 40° to 50° F. for varying periods of time; and, third, those relating to metastatic tumor tissue in patients whose general temperature had been reduced to subcritical levels between 74° and 90° F.

Relating to the first group of non-neoplastic or "normal" tissues, it may be said "a priori" that significant changes are the exception rather than the rule. In the series of 60 autopsies marked myocardial degeneration was found in 5 patients. In 3 of these it was associated with definite sclerosis of coronary arteries. In 3 patients acute pancreatitis was seen; these patients had been accustomed to take relatively large amounts of morphine. In 4 patients a significant and persistent fall in blood pressure was observed. In 3 of these there was extensive bilateral adrenal metastasis. Bronchopneumonia other than the terminal event commonly encountered in cases of advanced malignant disease appeared chiefly in the postrefrigeration period, in association with metastatic involvement of the lungs. Its occurrence with and its relationship to refrigeration, accordingly, is particularly difficult to evaluate.

With respect to the second group, temperatures of 40° to 50° F. applied locally to tumors regularly produced regressive changes going on to actual necrosis, even to the point of histologic clearance of the tissue of tumor cells in occasional instances.

In regard to the third group, the changes which were observed in metastatic tumor tissue from patients who were submitted to general reductions of temperature to 74° to 90° F. were similar in kind but varied greatly in degree in comparison with those resulting from application of the lower temperatures locally. In no case were regressive changes encountered until ninety-six to one hundred and twenty hours of refrigeration had been given, and in some cases no significant change seemed to occur even after three hundred hours of such low temperatures.

HYDATIDIFORM MOLE, Genesis of, Hertig, A. T., and Edmonds, H. W. Arch. Path. 30; 260, 1940.

A series of 1,027 spontaneously aborted ova and 74 hydatidiform moles has been studied with respect to the genesis of hydatidiform degeneration. Hydatidiform degeneration to some degree is common, occurring in 40 per cent of these spontaneously aborted ova, or in 4 per cent of all pregnancies. Typical stages in the evolution of a hydatidiform mole are described. A classic hydatidiform mole is uncommon, occurring only once in 2,062 full-term deliveries in this clinic.

Pathologic ova, of ten and two-tenths weeks' mean menstrual age, constituted 47.4 per cent of the total number of spontaneously aborted ova; 66.9 per cent of the pathologic ova showed early hydatidiform degeneration of the chorionic villi. "Nonpathologic" ova, of fifteen and four-tenths weeks' mean menstrual age, constituted 52.6 per cent of the total; 11.6 per cent of such ova showed early hydatidiform degeneration of their villi.

Hydatidiform degeneration of the chorionic villi of pathologic ova begins, in all probability, at about the fifth week of pregnancy, the time when the fetal circulation should begin to function. The fetal circulation in the chorion of the pathologic ovum fails to function because of extreme defectiveness or absence of the embryo. The vascular "anlagen" disappear coincidentally with the onset of hydatidiform degeneration, both processes being a function of absence or of defectiveness of the circulation.

Hydatidiform degeneration is prone to occur in the villi of early pathologic ova because the stroma of the villi is normally loose and their chorionic epithelium is normally active. Hydatidiform degeneration in the villi of early pathologic ova is an expression of continued physiologic activity of the trophoblast (absorption and/or secretion), with resultant accumulation of intravillous fluid, which cannot be utilized because of the lack of a functioning fetal circulation.

Hydatidiform degeneration is less likely to occur in "nonpathologic" ova because of a functioning fetal circulation of some weeks' duration, relatively dense stroma, and relatively inactive chorionic epithelium.

Transitional moles, of sixteen and six-tenths weeks' mean menstrual age, are usually typical pathologic ova containing no embryos, or at most extremely defective ones, although a few contain macerated normal embryos. Typical hydatidiform moles, of seventeen and four-tenths weeks' mean menstrual age, are true pathologic ova possessing no embryos or rarely a very defective one. A typical hydatidiform mole is, therefore, derived from a true pathologic ovum in which the embryo was either absent or very defective from the beginning and which, for reasons unknown, failed to abort at the usual time. Hence, it constitutes a type of "missed abortion."

BLOOD, Significance of Polymorphonuclear Toxic Index in Affections of the Musculo-Skeletal System, Sutro, C. J. Bull. Hosp. for Joint Dis. 1: 61, 1940.

In a survey of approximately 8,000 patients with affections of the musculo-skeletal system, it was found that, in certain cases, the estimation of the toxic index gave additional clinical information, especially in regard to differential diagnosis and prognosis. Since the evaluation of the toxic index is a simple procedure, its application to problems of differential diagnosis and prognosis is warranted.

(The index is equal to number of polymorphonuclear cells showing toxic granules divided by total number of polymorphonuclear cells and the product multiplied by 4.)

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

Experimental Poliomyelitis*

THE neutralization test is a method for determining the ability of immune serum to inactivate virus in vitro—in this instance, that of poliomyelitis. In their thorough review of the literature, the authors point out that though much information can be obtained from the test, the discrepancies and irregularities in results interfere with its effective application. The test is of practical value where qualitative determinations are desired, but it is unsuitable for quantitative studies.

In the second portion of the book, which is given over to a description of the author's carefully controlled experiments, a search was made for sufficient data for the development of a more refined and standardized technique. Unfortunately, their goal was not attained.

The final conclusions of the authors are that the test is a specific antigen-antibody reaction, but its presence does not necessarily imply resistance to infection. Since with the test in its present form quantitation is not a practical procedure, improvement or replacement of the neutralization test is desirable for the advancement of immunologic knowledge in poliomyelitis.

Neoplastic Diseases†

THE fact that this classic has now come into its fourth edition attests to the position it holds in the field of medical texts. The author has considerably revised many sections and completely rewritten some chapters.

The opening section on general oncology should be read by all doctors who have occasion to see malignancies, whether they be primarily interested in medicine or in surgery. The chapters on the nature of cancer and on experimental cancer research are particularly interesting.

The second, larger section on special oncology is a most complete and scholarly treatise on tumors of all types.

A book that should be in every physician's personal library, it is of equal value to the medical student, the internist, the surgeon, and the pathologist.

An Introduction to Biochemistry‡

IT IS of distinct benefit to the clinician from time to time to read through a book of this caliber. Although a small volume, it is comparatively comprehensive. The point of view entertained throughout is that biochemistry is an independent discipline related to the physiologic group on the one hand, and pure chemistry on the other.

*Experimental Poliomyelitis. I. A critical review of the literature with special reference to the use of the neutralization test in immunological studies. II. The Neutralization Test. A study of some factors involved in the neutralizing action of immune serum against poliomyelitis virus. By Morris Schaeffer, Ph.D., and Ralph S. Muckenfuss, M.D., Department of Health, Bureau of Laboratories, New York, N. Y. Cloth, 158 pages. Published under the Auspices of The National Foundation for Infantile Paralysis, 1940.

†Neoplastic Diseases. A Treatise on Tumors. By James Ewing, A.M., M.D., Sc.D., LL.D., Professor of Oncology at Cornell University Medical College, New York City; Consulting Pathologist, Memorial Hospital. Cloth, ed. 4, 1,160 pages, revised and enlarged, with 541 illustrations. W. B. Saunders Co., Philadelphia and London, 1940.

‡An Introduction to Biochemistry. By William Robert Fearon, M.A., Sc.D., M.B., F.I.C., Fellow of Trinity College, Dublin, Member of the Royal Irish Academy. Cloth, ed. 2, 415 pages, The C. V. Mosby Co., St. Louis, Mo., 1940.

After a rapid review of pertinent aspects of inorganic chemistry, the author turns to a more detailed study of organic compounds. Analytical methods are afforded their place in the discussion of each substance.

Written in an easy style, the book is graced by classical quotations some of which are especially apt. Over the index for instance, one sees "how index-learning turns no student pale, yet holds the eel of science by the tail" (Pope). This book may be heartily recommended.

Edible Wild Plants*

IF I AM ever lost in the forest and must subsist on what foods may be had from the wild plants about me, I shall want to have this book with me. It will tell me how to recognize and identify those wild plants which are edible, thus avoiding those which may be highly poisonous.

I will find a large variety for my menu, which will include 69 species of edible fruits and berries, 26 of salad plants and potherbs, 19 of roots and tubers, 15 of nuts, 13 of beverages and flavoring plants, 10 of seeds and seed pods, all minutely described, and a large number of others more briefly listed. Not only that, but if I am so fortunate as to have the book with me, I will find directions how to prepare or cook these plants.

There was a time when our pioneering ancestors realized the vital importance of this information. Now, when we are all eating cultivated foods, the knowledge has been all but lost.

Dr. Medsger has spent thirty years assembling the information recorded in his volume. It is profusely illustrated. It should be equally valuable to botanists and to those whose primary interest is in foods.

Compendium of Regional Diagnosis in Lesions of the Brain and Spinal Cord†

ACH year sees new books in medicine, each representing a new approach or interpretation. When the author's novel concept is good and is well grounded, the volume achieves popularity. With the lapse of time, others working in the same field may have better, more modern or more practical ideas concerning the presentation of the subject under discussion. When this occurs, the earlier texts, no matter how excellent they may have been, may pass into eclipse.

Some of them so adequately fulfill the need for which they were prepared that they outlive volumes which are submitted as more modern and may have been designed to supplant them. Such a work is Bing and Haymaker's regional diagnosis. After thirty years it still remains the preferred *vade mecum* for students for neuro-anatomy and neurologic localization.

There are several reasons. The authors' original manner of presentation filled a need. This having been achieved, there has been no attempt to pad successive editions, or to cover additional and less pertinent aspects. The book is still a small volume. The illustrations, many of which are in color, are quite completely descriptive and are sufficiently numerous to cover all phases of the subject. The general make-up of the book facilitates easy reading.

This volume is equally valuable to the freshman student learning neuro-anatomy, the neurologist and neurosurgeon, and the internist and general practitioner who require a ready reference work dealing primarily with the localization of lesions of the central nervous system.

*Edible Wild Plants. By Oliver Perry Medsger, Professor Emeritus of Nature Education, Pennsylvania State College. With an Introduction by Ernest Thompson Seton. Cloth, 225 pages, illustrated with 80 pen and ink drawings and 19 photographs, \$3.50. The Macmillan Co., New York, N. Y., 1939.

PROGRESS

FAMILIAL NONREAGINIC FOOD ALLERGY AS A PREDISPOSING CAUSE OF COMMON COLD

ARTHUR F. COCA, M.D., ORADELL, N. J.

THAT nonspecific influences may act as predisposing causes of common cold has been amply demonstrated in two of a brilliantly conceived series of studies on "Nonspecific Factors in Resistance" that have been carried out by Arthur Locke. These remarkable papers have had such scant attention in medical literature, and the conclusions reached in them are so directly applicable to the observations about to be described, that a summary of the outstanding pertinent results of Locke's findings is included here as follows:

SUMMARY OF LOCKE'S INVESTIGATIONS

1. Normal rabbits differ in the speed with which they can accomplish removal from the circulating blood of small numbers of intravenously injected type I pneumococci. Only those rabbits whose rate of removal of the injected pneumococci is faster than the rate of proliferation of the pneumococci survive the injection.
2. When normal rabbits are immersed in cold water until the body temperature has been reduced from the normal 102° to 103° F. to between 95° and 96° F., they differ according to the time required for a temperature recovery of 3° F.—"warming time." Those with fast recovery (warming times of 30 to 33) dispose of injections of small numbers of virulent type I pneumococci with a rapidity that permits a high percentage of survival. On the contrary, rabbits with a slow recovery (warming times longer than 45) are unable to remove the bacteria from the blood at a rate sufficient to assure survival.¹⁻⁴

As Locke points out, these methods of study are not applicable to man, but in his study of common cold he has made use of two other methods with

¹From the Lederle Laboratories, Inc., Pearl River, N. Y.

which he has obtained results that carry the same significance in principle as those of the rabbit experiments just described.

Locke determined the "oxygenation time" in a group of persons variously susceptible to common cold under conditions of physical stress which were produced by having the individual undertake a vigorous exercise of the muscles of the back, arms, and legs in a specially designed apparatus.⁵ The "oxygenation time" represents the rate at which oxygen is used up by the individual when he exerts himself to the utmost in the apparatus; the figure thus obtained is corrected according to the estimated body surface of the person.

In the "optimal response" A the "oxygenation time" was in the neighborhood of 0.60; it was shorter, e.g., 0.40 to 0.44, in the "hyperresponse" C' and longer, e.g., 0.79 and 0.85, in the "hyporesponse" C.

Under this procedure Locke found that among those persons classified as A ("optimal response") 74 per cent reported less than two colds during the year, whereas among the C group only 5 per cent had had less than two colds during the year.

Locke found also that, regardless of the classification determined in the individual previous to the onset of a cold, the grading at the time the attack began was C, and the condition of the person was that of "physical exhaustion and shock which a grading of C connotes." He states: "Common cold has less similarity to infections of the type producing small-pox, typhoid and diphtheria than with infections of the type observed as a result of invasion from the lungs and intestines in dogs and rabbits during transient exhaustion⁶ and shock."⁷

In a more recent study⁸ Locke has confirmed his general thesis that "low-grade infection (such as common cold) gains foot-hold because of impairment in the ability of the defense mechanisms to function." In this study he has used a method which spares the individual the physical strain that was involved in the determination of the oxygenation rate. This method requires the person merely to inhale 5 per cent carbon dioxide for one to two minutes. The inhalation of 5 per cent carbon dioxide causes a "measurable, reproducible and characteristic increase in the depth of breathing."

Defining the "ventilation quotient" as the ventilation rate, noted under the influence of carbon dioxide, divided by the basal ventilation rate (B.V.R.), as observed when the person is merely lying at rest, Locke proposed the figure 1.29 as the optimal ventilation quotient of a normally resistant individual. A group of persons showing ventilation quotients within 5 per cent of this optimum showed a much lower incidence of common cold than did the group showing ventilation quotients diverging 10 per cent or more from that optimum. One may again sum up Locke's results with his two methods as follows: there is a state of impaired physiologic function, the nature and cause of which is unknown, that can be detected in the individual through two quantitative methods; this state of impaired physiologic function may be found to affect some individuals at one time but not at another. Those individuals in

whom the impaired function is not found are less susceptible to colds than are those in whom it is found, and the impairment is always present at the onset of a cold.

These findings indicate that susceptibility to common cold is not due to a lack of the mechanism of defense but to a nonspecific impairment of the ability of the mechanism to function.

For a certain purpose, unrelated to the present inquiry, I made in September, 1939, a survey of 825 employees of Lederle Laboratories in Pearl River, N. Y., with respect to the incidence of common cold. These persons were kept under periodic observation in the winter and spring of 1939-1940. Among the 825 individuals 99 reported having had no colds in the past three years. Locke in Pittsburgh finds 12 per cent of unselected persons free of colds.

Fifty-two of these cold-free persons were selected for further examination because of their ready accessibility and their intelligence. Fifty-one persons who had a history of at least one cold* annually were similarly selected for examination.

Each individual of these two groups was repeatedly questioned as to the presence of food allergy† in himself and in his immediate family. In a few instances, when the inquiry took place shortly after a meal, the pulse rate was observed. This latter evidence was helpful, of course, only when the rate was high enough to be considered probably food allergic. The results of this examination are shown in Tables I and II.

Among the group of 51 persons who were subject to colds, there were three (W. K., W. Kw., and A. W.) who presented no personal history of food allergy; however, the high pulse rate of 96 observed in two of these men one hour after breakfast marks them as most probably food allergic. N. G., J. H., and P. P. gave a bilateral negative family history of symptoms of food allergy, yet there is no doubt that all three are themselves food allergic. The strongest point of evidence of food allergy in C. C. is the bilateral family history of food allergy. The evidence of food allergy in H. H., B. R., and E. W. is weak.

Acknowledging the possibility that A. W., C. C., H. H., B. R., and E. W. were not food allergic, one may draw from these data the conclusion that a large proportion, probably about 90 per cent, of cold-susceptible persons are food allergic. Among the 52 persons who had had no colds in the seasons of greatest risk of 1939-1940, and who reported having had no colds in the previous two years, 31 reported a negative family history, as contrasted with three such persons among the cold-susceptible group. Two others had sisters or brothers all of whom were free from food-allergic symptoms. Five others

*If the question should arise as to whether some of the group of cold-susceptible persons were individuals with perennial allergic coryza, it can be pointed out that since the group was not self-selected, but chosen at random, not more than 2 per cent (at most one or two individuals) could be expected to be so affected. Incidentally, one of the cold-free group has had allergic coryza in the winter, which has been controlled by specific treatment. This employee never mistook her condition for common cold.

†The cold-susceptible persons presented typical histories of an acute infectious coryza both as to clinical course and as to the characteristic change in the exudate.

†The expression "food allergy" throughout this paper refers only to familial nonreaginic sensitivity to food, a category which, according to evidence that will be presented in a later paper in this JOURNAL, must be separated from reaginic atopy (asthma, hay fever, atopic dermatitis).

reported a negative history in one parent. Twelve were unable for one or another reason to inquire of either parent about the matter, and only two gave a bilaterally positive family history of food allergy, as contrasted with eleven such persons in the cold-susceptible group.

The last seven of the cold-free group are no doubt food allergic, but mildly so, excepting possibly A. S. and E. W. The preceding four are questionable with regard to food allergy.

The comparison of the data in Tables I and II hardly permits any doubt as to the important role of food allergy in predisposing the person to common cold. Granting this conclusion, one can now appreciate fully Locke's application to his problem of the scientific method, in both design and technique, and also the accuracy of his deductions.

Throughout his study Locke seems to have been quite in the dark as to the nature of the original causes of the "nonspecific factors" of whose existence he was collecting such convincing evidence. Although the thought of allergy as a possible nonspecific influence evidently crossed his mind, it seems to have been set aside, no doubt because he was not aware of the large incidence of that state and had no method of detecting its presence.

Particularly illustrative of his correct insight is his forthright assertion "Probable nonspecific predisposition to common cold, at the time of test, is not identical with the probable future incidence." In the light of the result of our own investigation, this statement may be paraphrased as follows: the food-allergic state, which usually predisposes to common cold, may be present at the time of test in some persons who are not cold susceptible (see last cases in Table II).

For the question: What is the nature of the nonspecific predisposing cause of common cold? there is a suggestion that arises out of a very commonly observed phenomenon in food-allergic persons: namely, the rapid increase and equally rapid loss of weight which sometimes is noticed at the onset of a allergic headache and as the attack passes off. Some observers have reported that the loss of weight has been associated with an increase in the excretion of urine.

I have noticed this phenomenon in several persons with food allergy who symptoms were relieved by avoidance of the allergenic foods. In two persons, J. and A. P., urticaria was an outstanding symptom. After the allergenic foods were identified and eliminated, there was a permanent loss of several pounds in weight, although the diet was ample and well balanced and the general health was decidedly improved in both individuals. The rapid loss of weight in these cases is, of course, due to the withdrawal of fluid from the edematous tissues similar to that described by von Pirquet and Schick in the recovery from serum disease. This phenomenon is not limited to cases of urticaria so-called angioneurotic edema. The allergic infiltration of fluid into tissue is usually so distributed as not to be grossly perceptible.

From the foregoing considerations it is seen that in those cold-susceptible persons in whom food allergy is a predisposing cause of the susceptibility.

"nonspecific factor" of Locke may be the effect of allergic edema. This suggestion has some support in earlier published observations, as interpreted by Hoelzel⁹ and others. A number of investigators¹⁰⁻¹⁵ have reported that the incidence of colds is reduced by restriction of carbohydrate consumption. Hoelzel,¹⁰ McQuarrie,¹² and Higgins¹³ attributed the reduction in the number of colds to an observed lessening of tissue hydration.

There must be other predisposing causes of susceptibility besides food allergy. This conclusion seems forced by the fact that, although between 20 and 25 per cent of white families are free of food allergy,* only 12 per cent are quite free of common cold, and a few of these are food allergic.

SUMMARY

Evidence is offered of the importance of food allergy as a predisposing cause of common cold.

CLINICAL AND EXPERIMENTAL

THE DETERMINATION OF BLOOD VELOCITY BY LOBELINE*

FRANK V. PICCIONE, M.D., AND LINN J. BOYD, M.D., F.A.C.P.
NEW YORK, N. Y.

DURING an investigation of the pharmacologic properties of lobeline, the "circulation time" of 95 individuals was determined by this substance. In this communication discussion will be limited to directing attention to a new method of ascertaining the end point of the test and to reporting an additional series of patients studied by this means.

The original contribution of Teplov and Sor,¹ based upon the study of 165 patients, indicated that lobeline provided an objective method for the determination of circulation time. The end point (cough) was striking and brief, the procedure simple, the drug free from toxicity, and the result susceptible to graphic registration. When less than 0.03 to 0.04 mg. of lobeline (or less than 0.08 to 0.12 mg. of synthetic lobeline) per kilogram was employed intravenously, respiration was altered at times; with this dose they noted brief apnea, a cough, and then transient polypnea. Cough was elicited in 60 to 70 per cent of the patients; the percentage of successful results was increased by repetition of the test after 15 to 20 minutes with a slightly larger dose. If cough still failed to occur, the polypnea was registered by a pneumograph in order to obtain an objective end point.

Volgin and Stanojevič² alone observed 49 patients, and with Djordjevič³ they studied 80 individuals. Stanojevič⁴ participated in 500 determinations on 150 patients. Lobeline was used exclusively, and only 7 patients failed to respond with cough; the dosage was individualized but did not exceed 0.07 mg. per kilogram. The circulation time amounted to 10.3 seconds in the average normal adult (Teplov and Sor, 13.4 seconds), to 12.4 seconds in miscellaneous patients; in patients with cardiac compensation it was 13.4 and in those with cardiac decompensation it was 30.2 seconds (Teplov and Sor, 40 seconds). On the basis of 140 determinations Evzlin⁵ concluded that the method was objective, free from unpleasant concomitant manifestations, uniform in its results, and harmless to patients. Trimarchi,⁶ employing lobeline up to 0.18 mg. per kilogram of body weight, reached a similar conclusion. Large amounts seemed necessary in some cases of auricular fibrillation; when the maximal dose was employed, precordial pain and dyspnea developed in some cases, lasted for a few seconds, and vanished without sequelae.

During preliminary experiments arranged to familiarize ourselves with the method, we noted that patients often commented upon a peculiar sensation in the throat ("tickling"); this may or may not be accompanied by cough.

Twenty males whose ages varied from 13 to 64 years and whose weights ranged from 90 to 175 pounds comprised this group. Most of them were suffering from gonococcal urethritis and a few from pes planus. None of them had cough as a symptom. The tests

*From the Department of Medicine (Metropolitan Hospital Service), New York Medical College, Flower and Fifth Avenue Hospitals.

Received for publication, November 10, 1939.

were conducted under basal conditions and at the same time of day. Patients imagined they were receiving some therapy. Each of them, regardless of age or weight, received 3 mg. of lobeline intravenously. After the injection they were asked whether they felt anything. If nothing occurred, the test was repeated with 6 mg. of lobeline.

When 3 mg. of lobeline were administered, 9 patients had tickling in the throat, 6 had cough, and 5 had no response. When 6 mg. of lobeline were given to the 9 people who had tickling, 6 responded with cough and 3 with more pronounced tickling. Among the 5 with no response, 3 developed tickling and 2 cough with the larger dose. In short, 15 of 20 patients had an objective response, and the remainder had a reaction which made the end point easily recognized. No ill effects followed.

These results suggest that the intravenous injection of lobeline in doses of from 3 to 6 mg. provides a dependable reaction for the objective determination of circulation in 75 per cent of patients. Employment of an additional subjective symptom practically eliminates negative responses when the larger dose is given.

The circulation time of 75 individuals suffering from various illnesses was then determined.

Alpha-lobeline was employed exclusively. Since 1 c.c. ampoules contain 0.01 Gm., 0.1 c.c. corresponds to 1 mg., and no difficulty is encountered in calculation of dose. Moreover, the volume of the solution is small and the time required for injection is short. Although 5 mg. will usually elicit a response, 3 to 7 mg. were employed in accordance with the weight. (Trimarchi has injected 11 mg. in persons with severe cardiac disease.)

Patients were asked to lie as flat as possible, to relax, and not to hold the breath. The stomach must be empty. The purpose of the test is fully explained to dispel any fear. A tourniquet may be applied to the arm to assist in visualization of the vein, but it should be removed prior to the injection. The injection time should not exceed two seconds. The starting point of the time was placed at the moment the plunger struck the bottom of the syringe; the end point was considered the elevation of the hand or the cough. An ordinary stop watch was employed. A 23-gauge needle, 1 inch in length, was found to be most suitable. No patient experienced any pain; a few times some of the solution spilled into the paravenous tissues but no inconvenience or symptoms resulted. No patient objected to a repetition of the test. Three patients violated the rule of an empty stomach and ate fruit one-half hour before the injection. One did not respond at all; the second responded after fifty seconds, although an eight-second circulation time was obtained on the following day; the third, who had a decompensated cardiac involvement with a prolonged circulation time, showed excessive prolongation (more than one minute), then coughed and vomited.

With small doses (3 to 4 mg.) the rate and depth of respiration may change. However, usually this cannot be employed as an end point since the first alteration of respiration may not be recognizable. Tracings of the respiratory excursion can be secured, but a necessity for any special device defeats general employment of the test.

A peculiar sensation in the throat precedes or accompanies the cough. The occurrence of this sensation may be accompanied by a grimace. The sensation is described in various manners, but usually as tickling or "something coming up quick in the throat." At all events it is perceived as something unusual. Patients were instructed to raise their hand as soon as they felt anything; usually cough occurred while the hand was being elevated. If there is an interval between the two phenomena, not more than one or two seconds separate them.

The cough resembles the explosive cough caused by the inhalation of smoke or dust. It is not severe nor does it distress patients in any way. Individuals suffering from bronchiectasis, pneumoconiosis, or pulmonary tuberculosis, said that the cough was un-

usual and sounded different. Occasionally the patient asked for a sip of water "to fix the throat" which "felt dry." Three patients noted moderate dyspnea; one patient reported a sensation of choking, although no dyspnea was observed. Many individuals experienced an improvement of respiration, were pleased with the injection, and the momentary cough was attributed to nervousness.

No members of the other groups to be reported were normal, but many of them sought treatment for trivial conditions, such as pes cavus and bursitis, which may be regarded as having no bearing on circulation. Physical examination of this group yielded normal findings in the lungs and cardiovascular system. Patients with important affections not involving the heart or respiratory system were also examined. They were considered normal from the cardiovascular standpoint.

In many the venous pressure was estimated by the degree of engorgement of the veins of the neck and the level at which the arm veins collapsed upon elevation of the limb. Exact measurement was regarded as unnecessary. Vital capacity was determined by the usual apparatus, but it did not constitute a part of the test.

Group 1.—Six patients, 5 females and one male, formed this group. Their ages ranged from 22 to 52 years. Four had secondary anemia and tuberculosis, one had a secondary anemia and subacute bacterial endocarditis without cardiac decompensation, and one had pernicious anemia. The hemoglobin estimations in the group ranged from 60 to 65 per cent; the red blood cells did not vary more than 200,000 from three million.

The circulation time in this group of patients who had anemia varied from three and one-half to eight seconds. The two shortest circulation times in the entire series occurred in this group.

Group 2.—Twenty-three patients, 13 males and 10 females, were placed in this group. Their ages varied from 13 to 60 years. Only one patient had a cardiovascular anomaly (cirrhosis of the liver, pulmonary emphysema, and possible beriberi heart. There was some peripheral edema. His circulation time was eight seconds).

The average circulation time in this group of patients who had no anemia, no cardiovascular disease (one exception), but definite illnesses, was 8.3 seconds. One individual (tonsillitis) had a circulation time of twenty seconds but no demonstrable cardiovascular involvement. Individuals with manifest thyrotoxicosis (two observations) had times of five and nine seconds. With the one exception noted the extremes of this group were five to twelve seconds.

Group 3a.—Two males and one female, whose ages varied from 22 to 62, suffered from mild, moderate, and severe pulmonary fibrosis, associated with pneumoconiosis; two of them had electrocardiographic alterations as well. The circulation times of these patients ranged from six to nine seconds. The patient with the lowest vital capacity had the shortest circulation time.

Group 3b.—Three male patients, whose ages were 32, 39, 41, had pneumothorax (one pyopneumothorax). The circulation times ranged from seven to fourteen seconds. The individual with the longest circulation time had a Peabody factor only slightly inferior to that of the patient with a circulation time of seven seconds. There seemed to be no relationship between the Peabody factor and circulation.

Group 3c.—Eleven patients, 8 males and 3 females, comprised this group. Their ages varied from 23 to 79. They suffered from various chest diseases, such as pneumonia, pulmonary

malignancy, and caseous pneumonic tuberculosis. The circulation times ranged from six to ten seconds. The patient with the longest circulation time had pneumonia. The patients with the lowest Peabody factors (3.6, 3.3) had shorter circulation times than a patient with a much higher Peabody factor (5.6). Although cough and dyspnea were present in pulmonary malignancy, the circulation time was eight seconds.

Among 17 patients presenting various diseases of the lungs, the circulation time varied from six to fourteen seconds. Dyspnea of pulmonary origin did not prolong the circulation time.

Group 4a.—Three males and 2 females were placed in this division. Four suffered from rheumatic heart disease, and one from syphilitic aortic valve insufficiency. One patient had cardiac compensation (ten-second circulation time). Two patients had auricular fibrillation (circulation times of twenty-five and twenty-eight seconds). In the 4 patients with cardiac decompensation the extremes of circulation time were from sixteen to twenty-eight seconds.

Group 4b.—Six males and 7 females, whose ages ranged from 32 to 71, were placed in this class. All of them had hypertension and some had suggestive evidence of coronary artery disease. The circulation times varied from twelve to thirty-five seconds. The patient with the shortest circulation time was able to lie perfectly flat, but she had some dyspnea on walking (very obese woman). Patients with circulation times of fourteen to seventeen seconds "had to sleep with pillows," were "short of breath at night," or had dyspnea on walking. Those with circulation times of seventeen to thirty-five seconds had definite cardiac decompensation.

Group 4c.—This division contained 11 patients, 9 males and 2 females. The ages varied from 44 to 83. They all had marked evidence of coronary artery disease. Two had auricular fibrillation, one had angina pectoris, and two had survived coronary thrombosis. The circulation times in the group ranged from eleven to forty seconds. The group with the eleven- to sixteen-second circulation time was composed as follows: 2 without symptoms (the oldest patients) gave responses at eleven and fifteen seconds; one with recent coronary thrombosis, without evidence of cardiac decompensation, at thirteen seconds; one with recently recovered cardiac compensation, at fourteen seconds; one with slight dyspnea, at sixteen seconds. The remainder obviously had cardiac decompensation and their circulation times ranged from twenty to forty seconds.

Patients with cardiac decompensation showed a definite prolongation of the circulation time. Circulation times above twenty seconds were always associated with cardiac decompensation, but one patient with unproved but probable cardiac decompensation (group 2) had a circulation time of eight seconds. On the contrary, patients with a wide assortment of diseases (one exception) did not have circulation times above sixteen seconds. This exception appears quite important and suggests that exceptions occur in both directions, namely, normal circulation time in rare cases despite cardiac decompensation and prolonged circulation time despite the absence of cardiac decompensation. These exceptions imply that this (and other similar tests) are far from infallible and cause one to doubt their application to the diagnosis of cardiac decompensation. In short, one wonders whether they are sufficiently delicate to be suggestive in early cardiac decompensation and whether they are necessary in manifest cardiac decompensation.

Nevertheless, repetitions of the test showed increased velocity of the blood stream as improvement occurred in cardiac decompensation; when the circulation time remained status quo the general situation persisted unchanged. For

example, the circulation times at two-week intervals in one individual with cardiac decompensation were thirty, twenty-two, fifteen seconds, respectively, as he improved. One patient with cardiac decompensation had a circulation time of twenty-five seconds; one and two weeks later the same reading was obtained and no recognizable change occurred in the situation during the interim. Similar results were obtained in numerous other individuals.

Volgin and Stanojević compared the circulation time obtained with lobeline with that secured by decholin and saccharin. They found the circulation time in all groups was longer with the decholin and saccharin and that variations were greater within each of the various groups, i.e., among normal individuals and among patients with cardiac decompensation. The longer time might be partly explained by the difference in the mechanism, that is, decholin and saccharin are arm-tongue methods, whereas lobeline is an arm-carotid sinus method. The results obtained by decholin and saccharin are similar, and the discrepancy in comparison to lobeline is greatest in patients with cardiac decompensation. A study of lobeline and calcium gluconate indicates that the circulation time with the former is shorter than with the latter. In ten experiments the lobeline time was one to seven seconds shorter than the calcium gluconate time in nine patients; the calcium gluconate time was shorter than the lobeline by two seconds in one patient.

A review of all the results obtained indicates that a sharp line cannot be drawn between individuals whose circulation is normal and those with cardiac decompensation by means of the circulation time. Nevertheless, several observations seem worthy of mention.

Many patients with pulmonary tuberculosis, bronchiogenic carcinoma, pleurisy, pneumothorax or anemia, exhibited dyspnea at rest or upon exertion. The circulation time was not prolonged in any of these individuals as long as cardiac decompensation was absent. Accordingly, it seems that the test may have value in assisting to differentiate between dyspneas of cardiac and pulmonary origin.

The degree of edema and the height of the venous pressure did not parallel the circulation time. In two patients who suffered from hypertension and who had marked anasarca and increased venous pressures (three plus), the circulation times were seventeen seconds in one and thirty-four seconds in the other. One patient with cirrhosis of the liver and possible beriberi heart had edema of the abdominal wall and of the lower extremities and increased venous pressure (one plus), although the circulation time was eight seconds. The circulation time does not seem to be correlated with the degree of failure of the right side of the heart, but bears a relation to left-sided decompensation. Since the occurrence of edema and the increase of venous pressure coincide with the failure of the right ventricle (other causes being excluded), the height of the venous pressure bears no relation to the circulation time. In fact, patients with normal venous pressures showed a greater circulation time than those with very high venous pressures (two and three plus). One individual with the high venous pressure (three plus) had the same prolongation of circulation time (thirty-four seconds) as another with a slight increase (one plus).

A vital capacity as low as 550 was found in a patient with a circulation time of six seconds. The patient had pulmonary fibrosis but no cardiac failure.

Another patient with a vital capacity of 3,400 and a Peabody factor of 7.5 showed a circulation time of eighteen seconds; still another individual with a vital capacity of 1,200 and a Peabody factor of 2.7 had a circulation time of eight seconds. Reductions of vital capacity not of cardiac origin do not seem to influence the circulation time.

Circulation times between three and thirteen seconds were recorded in patients with no myocardial failure. Circulation times of twenty-four seconds or more occur in persons with cardiac decompensation. Normal persons with compensated heart disease or with incipient myocardial failure had circulation times of fourteen to twenty-four seconds. The longest circulation time in a person without cardiac involvement (tonsillitis) was twenty seconds; the average for all those without cardiac disturbance was eleven seconds. The shortest circulation time in the presence of indisputable myocardial failure was thirteen seconds, the longest was forty seconds, and the average was twenty-seven seconds. Accordingly, the method cannot be employed to determine the existence of circulatory failure. However, it may assist in the differential diagnosis of dyspnea and in the determination of the therapeutic progress of a patient.

It does not seem advisable to enter into a discussion of the mechanisms thought to be involved in the lobeline test since the problem has not been completely solved. However, the weight of evidence strongly favors the participation of the carotid sinus in the response. Accordingly, the lobeline and sodium cyanide methods for the determination of the circulation time are closely allied.

SUMMARY

Lobeline was employed for the determination of the circulation time in 95 patients. The absence of intolerance, toxicity, or emutation noted by other observers found further confirmation. A new subjective response was observed; this "tickling" sensation as the end point may be employed when cough is present and might be confused with the lobeline cough; it also makes the test applicable without recourse to special devices and permits a definite result to be obtained in practically all cases.

The objectivity of the lobeline test endows it with certain definite advantages over some other substances employed for the same purpose. However, in determination of the existence of cardiac decompensation, it possesses those disadvantages which are intrinsic to any "circulation time" method. As an objective means of differentiating dyspnea of left ventricular origin and that of pulmonary origin, and as an aid in following the course of therapy, it may provide some very useful information.

REPORT OF A CASE OF CONGENITAL ABSENCE OF THE SPLEEN AND CHRONIC AMNIOTIC FLUID PNEUMONIA

RICHARD L. NELSON, M.D., F.A.A.P., AND D. R. VENABLE, A.B., M.D.
WICHITA FALLS, TEXAS

THE congenital anomaly herein reported is not common, judging from the comparatively few such cases found in the literature. During the past ten years we were able to find only five reported cases of congenital absence of the spleen, and only one of these was in an American journal, the interesting account by M. S. Peterman in the *Journal of the American Medical Association* for October 8, 1932, of a double anomaly, the absence of both spleen and left kidney. The history of apparent constitutional inferiority that the author gave in this case is very similar to the history of the fourteen-month-old boy upon whom we performed a necropsy.

The child was resuscitated with considerable difficulty at birth, having aspirated a large amount of mucus and amniotic fluid. Examination twelve hours after delivery revealed a listless, cyanotic baby, with a weak cry and an inability to nurse, although he weighed nine pounds and was a full-term child. Coarse râles were heard over both lungs, and he seemed to breathe with considerable difficulty. The heart was normal to auscultation and percussion. At three weeks of age an x-ray examination of the chest showed marked increase in pulmonary markings, but no enlargement of the thymic shadow. The heart was normal in size, shape, and position. At this time no râles could be heard over the lungs, but the infant continued to be cyanotic; he had little appetite, and was quite feeble. When he was six months old, he developed an attack of bronchopneumonia and was acutely ill for several days. He recovered from this but continued to be marasmic and the peculiar cyanosis persisted. He was not seen again until three days prior to his death, when the mother noticed that his left foot was cold and clammy and showed a bluish discoloration. He had some fever at this time. He became rapidly worse and developed a temperature of 102.6° F., rapid respirations, and rapid pulse rate. The heart was enlarged to the left, with a heaving impulse and a blowing systolic murmur at the apex. The liver margin could be felt one and one-half fingerbreadths below the costal margin. The spleen could not be palpated. The lungs were clear. An electrocardiogram showed right axis deviation and tachycardia. The lower third of the left leg and the left foot were cold and purple, with a sharply marked border indicating beginning gangrene. No pulsation could be felt in the anterior tibial artery. Blood cultures and other indicated laboratory procedures were omitted out of deference to the parents' wishes, since it was so evident that death was imminent. Local and supportive

treatment were of no avail, and the child died the following day. Just prior to death the temperature rose to 106° F., and the pulse rate was so rapid it could not be counted.

The necropsy showed a fairly well-nourished infant. The lower third of his left foot and his left leg were gangrenous due to thrombosis of the blood vessels. The lungs appeared firmer than normal and microscopic sections showed a peculiar condition in that many of the alveoli were obliterated by fibrous connective tissue; the walls of the functioning ones were very thick, probably the result of the amniotic fluid pneumonia that the infant had at birth. The heart was greatly dilated and the pericardial sac contained about twice the normal amount of fluid which was blood-stained but not purulent. There were fresh vegetations on the mitral valves which also showed other evidence of acute inflammation. The other valves were normal. There was no evidence of any congenital anomaly of the heart which might have accounted for the cyanosis that was present throughout the child's life. A large ante-mortem clot, which was firmly adherent to the chorda tendineae and showed beginning organization, was found in the left ventricle. There were fibroblasts present as well as polymorphonuclear leucocytes and some lymphocytes. The liver was large and congested, and the liver cells showed albuminous and fatty degeneration. The kidneys showed similar changes but to a much less degree. The gastrointestinal tract and pancreas were normal. A thorough search failed to reveal a spleen, although all the viscera were removed from the abdomen. An unsuccessful attempt was made to locate a splenic anlage by following up the branches of the celiac artery, but no such vessel was present. Acute bacterial endocarditis with emboli to the blood vessels of the lower third of the left leg and the left foot and the resulting thrombosis were the immediate cause of the death of the infant. Just what part, if any, the congenital absence of the spleen could have played in the production of the marked cyanosis that persisted throughout this child's brief life is an interesting speculation. Since the spleen is such an important organ in the hematopoietic system, it is conceivable that its congenital absence might have exerted a profound and adverse influence upon the circulatory system or, for that matter, upon the whole constitutional well-being of the child.

THE PHARMACOLOGY OF SILICA*

EFFECTS AND MECHANISM OF ACTION OF FATAL INTRAVENOUS DOSES OF SILICIC ACID

WALTER MODEL, M.D., AND CHARLES SALZMAN, B.S., NEW YORK, N. Y.

THE study presented here is part of a larger project on the nature of silicosis. The exact form of silica which produces silicosis is not known, but there is evidence that silicic acid may play a role as an intermediary chemical agent in the development of the disease.¹ We shall deal here with the results of an investigation of the pharmacology of silicic acid† and give special consideration to the following: I. Toxic and lethal dose. II. Systemic effects. III. Mechanism: (a) role of blood clot formation and (b) site of action. IV. Significance of the colloidal nature of silicic acid.

METHOD

Cats were used in our experiments. Silicic acid sol was the only form of colloidal silica examined. It was prepared by dissolving suitable amounts of sodium silicate in water and treating with an excess of hydrochloric acid. This was dialyzed against water until free of chlorides and then concentrated to somewhat more than 1 per cent by evaporation with heat under reduced pressure. The silicon dioxide content was determined gravimetrically by drying and blast burning. The solution was then diluted to 1 per cent‡ and sufficient sodium chloride was added to make an 0.85 per cent saline concentration. A small amount of hydrochloric acid was added to retard the development of gel. The solutions were stored in a refrigerator when not in use. All solutions were slightly opalescent at the outset but no gel was visible macroscopically. The pH of each batch was determined electrometrically. This varied with each specimen. The same batch of silicic acid was used in each series of experiments.

The cats were anesthetized with sodium amytal by the intravenous or the intraperitoneal route, usually the former in doses of 40 mg. per kilogram.§ In most experiments kymographic records were made of the effects of silicic acid on blood pressure, heart rate, and respiration, although some observations were made on intact unanesthetized animals. Electrocardiographic records were made

*From the Department of Pharmacology, Cornell University Medical College, New York. This study was made under the provisions of a Works Progress Administration Project sponsored by the Department of Health of New York City, and carried out by the Cornell University Medical College, New York Hospital, and the Industrial Hygiene Committee of the New York Tuberculosis and Health Association acting as cooperating agencies.

Received for publication, December 5, 1939.

†The terms silicic acid and colloidal silica will be used interchangeably.

‡Batches 1 and 6 were made up as 0.75 per cent and 2.0 per cent, respectively. The amount of silicic acid is always expressed in terms of silicon dioxide content.

§All doses are considered in relation to body weight, but for purposes of convenience the phrase, "per kilogram," will be omitted.

in some experiments. Silicic acid was always administered intravenously. In order to prevent the formation of intravascular clots and clots in the recording system, an anticoagulant dye was used in all but a few stated experiments. This procedure is discussed later.

All animals were examined after death. Sections of tissue were preserved for microscopic examination, but the results of this examination will form part of another report.

EXPERIMENTAL

I. Toxic and Lethal Dose.—The lethal dose of silicic acid was determined by continuous intravenous injection. The injection was stopped when blood pressure fell to about a level of 100 mm. Hg, since such falls were almost always fatal. However, more silicic acid was administered if necessary. The animals were anesthetized and the blood pressure was recorded from the carotid artery. The rate of intravenous injection was varied to determine what role the rate of administration might play in the toxicity of silicic acid.

Great variability of the fatal dose of silicic acid within each batch and between batches was a prominent feature. The average lethal dose of batches varied from 15 mg. to 193 mg. The smallest single fatal dose was 5 mg. and the largest was 284 mg. The lethal dose within each batch, however, remained in the same general range. Thus, in the batch in which 5 mg. was lethal in one case, the largest dose was 20 mg., while in the batch in which 284 mg. was the largest dose, the smallest dose was 142 mg. Lethal doses of the same specimen of silicic acid varied as much as 100 per cent on the same day, ruling out the possibility that a change in the silicic acid had occurred. The toxic dose (i.e. the dose necessary to produce a perceptible fall in blood pressure) was as variable as the lethal dose; generally it was about 60 per cent of the lethal dose.

TABLE I

TABULATION OF PH OF SPECIMENS OF SILICIC ACID AND THE LETHAL DOSE

BATCH NO.	pH	AVG. L. D. MG./KG.	NO. CATS
4	1.53	165	8
1	1.55	15	2

2	1.78	15	3
3	1.87	30	2
6	2.40	152	10
5	2.65	193	14

The pH of the different batches of silicic acid varied between 1.53 and 2.65. Table I indicates the absence of correlation between the lethal dose and the pH. In addition, preliminary experiments with salt solutions, to which hydrochloric acid had been added to produce the same pH as that of the silicic acid specimens used in our experiments, indicated that the acidity itself was without any effect in the amounts used.

From the results in Table II it appears that the more rapid injections required larger amounts of silicic acid to produce death, but this may be due to a latent period in the development of the effects of silicic acid, so that the end

point was passed in the titration. In Table III, however, in which data for the lethal dose and the rate of administration for all experiments with two batches of silicic acid are given, there appears to be no significant correlation with the injection rate.

II. Systemic Effects.—The effects produced by all batches of silicic acid were qualitatively the same. In unanesthetized animals it produced an acceleration of respiration, which in the case of fatal doses was followed by progressive weakness and finally clonic convulsions. In the fatal cases the entire sequence of events usually occurred within five minutes after the injection.

point was passed in the titration. In Table III, however, in which data for lethal dose and the rate of administration for all experiments with two batches of silicic acid are given, there appears to be no significant correlation with injection rate.

II. Systemic Effects.—The effects produced by all batches of silicic acid were qualitatively the same. In unanesthetized animals it produced an acceleration of respiration, which in the case of fatal doses was followed by progressive weakness and finally clonic convulsions. In the fatal cases the entire sequence of events usually occurred within five minutes after the injection.

Fig. 3.—Effect of silicic acid on intrapulmonary blood pressure. The first dose raises the systolic level of intrapulmonary blood pressure and causes a slight drop in systemic blood pressure. The second dose causes a rise in the diastolic level of intrapulmonary blood pressure and a sharp fall in systemic blood pressure.

Fig. 4.—Effect of sillicic acid when injected into the left auricle. The first dose administered intravenously produces a rise in both systolic and diastolic levels of intrapulmonic blood pressure, while a subsequent dose, four times as great, injected into the left auricle produces only an almost imperceptible rise in the systolic level of intrapulmonic blood pressure. The third dose injected intravenously, the same size as the first, is fatal.

Fig. 5.—Effect of protection of lung from silicic acid. *Cl.* closing of left branch of pulmonary artery; *Uncl.*, opening of left branch of pulmonary artery; *Opn.*, opening of right branch of pulmonary artery; *C.* closing of left branch of pulmonary artery before and silicic acid is injected; *Opn.*, opening of left branch of pulmonary artery after silicic acid is injected; *A.* closing of systemic blood pressure. Opening restores to original level. *B.* closing of left pulmonary artery; *C.* injection of silicic acid with left lung out of circulation produces rise in pulmonary blood pressure and fall in systemic blood pressure; *D.* opening of left pulmonary artery. Blood pressure levels return to normal. *E.* closing of left pulmonary artery now produces greater rise in pulmonary blood pressure and fall in systemic blood pressure than in control (*A*); *F.* additional dose of silicic acid with left pulmonary artery closed produces more marked effect than before (as in *C*); *G.* now closing of pulmonary artery produces more pronounced effects on blood pressure than before, as in *A* and *E*; *H.* still more pronounced effects from another dose of silicic acid, with only slight recovery after opening of pulmonary artery.

tricle or block in the pulmonary circulation. The following observations were made in experiments designed to shed light on this question:

When silicic acid is injected intravenously, it reaches the right ventricle in relatively high concentration. It is conceivable, therefore, that the right ventricular muscle is damaged by the concentrated acid reaching it. Injections of silicic acid, therefore, were made into the left auricle, so that the acid reached the left ventricle before it circulated through the body. Such injections produced the same effects as the intravenous injections; namely, distention of the right side of the heart, rise in intrapulmonic blood pressure, and fall in systemic blood pressure. The only noticeable difference was that considerably more silicic acid was required to produce the same effects than was required with intravenous injections. Four times the dose which when injected intravenously produced marked changes in intrapulmonary pressure, was without effect when injected into the left auricle (Fig. 4).

It was also noted in a series of experiments that silicic acid was 25 per cent more toxic when the circulation of the left lung was ligated than when both lungs were intact. In another type of experiment (Fig. 5) the circulation of the left lung was constricted while silicic acid was being injected, and was re-opened after the injection had been completed. Thus the left lung was temporarily protected from the effects of silicic acid. The injection produced a rise in intrapulmonary pressure (recorded from the right ventricle) and a fall in systemic pressure. As soon as the protected lung was restored to the lesser circulation, both the intrapulmonary and systemic blood pressures tended toward normal. This protection against the effects of silicic acid was in evidence until massive (fatal) doses were given, when the protection afforded was only temporary. Control observations indicated that the constriction of the circulation to the left lung was itself without appreciable effect, whereas after the administration of silicic acid this procedure produced a definite rise in intrapulmonary and a fall in systemic blood pressures.

IV. Significance of the Colloidal Nature of Silicic Acid.—Inasmuch as silicic acid is a colloid and it has been demonstrated by Hanzlik⁴ that colloids because of their physical nature can exert systemic effects, it was decided to determine whether the colloidal nature of silicic acid played any role in the effects observed.

Cats were injected with solutions of egg albumen, agar-agar, and acacia. Sufficiently large doses of these substances produced a fall in systemic pressure and an acceleration of respiration. However, in experiments with egg albumen and acacia, in which intrapulmonary blood pressure was determined, the initial effect was a rise in systemic pressure and not a rise in intrapulmonary pressure (Fig. 6).

Egg albumen does, however, exert a synergistic action on silicic acid. An initial dose of egg albumen (300 mg.), which produced only a transient fall in systemic blood pressure, considerably increased the toxicity of silicic acid administered two to three minutes later. In 8 cats the lethal dose of silicic acid averaged 165 mg., whereas after egg albumen the lethal dose of the same specimen for 7 cats averaged only 45 mg. In another series the control lethal dose of

Fig. 6.—Effects of egg albumen and gum acacia on systemic blood pressure and pulmonary blood pressure.

silicic acid was 193 mg., and after egg albumen it was 110 mg. In both series the effects following the combination were the same as those following silicic acid alone.

DISCUSSION

The physical and chemical relationship between silicic acid and silica is very close; it has been claimed that silicic acid is hydrated silica,⁵ and x-ray diffraction observations indicate that the atomic mosaic of both is very similar if not identical.⁶ Gye and Purdy² have shown that silicic acid may, if administered over a long period of time, produce anatomical changes in organs other than the lungs, which are in many respects similar to those seen in the lungs in silicosis.

The lethal dose of silicic acid was very variable. There is no evidence that either the pH of the solutions used or the rate of administration of silicic acid played any role in the variable toxicity.

In the studies by Gye and Purdy it was demonstrated that death after intravenous injections of silicic acid was accompanied by massive intravascular clotting. These clots filled the chambers of the heart and many of the large veins. On the basis of other experiments these workers concluded that while clotting was the cause of death, it was secondary to endothelial damage. In our experiments it was demonstrated that the lethal dose and the toxic effects of silicic acid are not affected when the formation of clots is prevented by the use of an anticoagulant. It may be concluded, therefore, that while intravascular clotting may cause or contribute to the fatal outcome, there is another more direct action of silicic acid which may cause death.

The picture produced by ligation of the pulmonary artery, namely, distention of the right side of the heart, empty left side, rise in pulmonary blood pressure, and fall in systemic blood pressure, is exactly reproduced by the intravenous administration of silicic acid. The best explanation available for the production of the toxic effects of silicic acid is that it constricts the blood vessels of the lungs.

The question whether the effects of silicic acid are due to its chemical or physical nature is still an open one. Experiments by Hanzlik⁴ indicate that colloids in general may produce marked changes in systemic blood pressure, but no colloid other than silicic acid has been demonstrated to produce an initial rise in intrapulmonary blood pressure. However, the synergism between silicic acid and egg albumen is suggestive of some common action.

SUMMARY AND CONCLUSIONS

Silicic acid solutions, prepared according to a standard procedure, differed markedly in their toxicity when injected intravenously into cats. The average lethal dose of different batches varied from 15 to 193 mg. per kilogram, and was not appreciably affected by wide range in pH or rate of injection.

Immediately following injection there was a rise in intrapulmonary arterial pressure and a fall in systemic blood pressure, with an accompanying engorgement of the right side of the heart and an empty left side. Similar changes followed when silicic acid first passed through the systemic capillary bed, as was the case when injection was made directly into the left auricle.

The effects on the lung circulation were not influenced by the use of an anticoagulant, and, therefore, they were not caused by intravascular clotting. Nor is it likely, in view of the selective action on the lung capillaries and the failure of

other colloidal substances (egg albumen, agar-agar, and acacia) to produce similar changes, that they represent a nonspecific colloidal effect of silicic acid.

It is concluded that silicic acid exerts a selective action on the capillary bed of the lungs which results in an increased resistance to blood flow and accounts for the toxic symptoms and death.

TOXIC HEPATITIS DUE TO SULFANILAMIDE*

REPORT OF A FATAL CASE WITH HISTOPATHOLOGIC FINDINGS IN THE LIVER

S. S. BERGER, M.D., AND H. S. APPLEBAUM, M.D.

CLEVELAND, OHIO

THAT sulfanilamide has toxic effects is generally known. That it may cause hepatitis has been stressed by several observers. Hageman and Blake¹ have observed a case of toxic hepatitis, presumably due to sulfanilamide, in an alcoholic person. Saphirstein² recorded a severe but nonfatal case of hepatitis. Long³ encountered jaundice with marked decrease in liver function on one occasion. Bannick, Brown, and Foster⁴ reported two fatal cases of hepatitis in which they believed pre-existent liver damage a possibility. Garvin⁵ recorded a series of five cases of hepatitis, one of which proved fatal, but no autopsy was obtained. Cline⁶ was the first to place on record a case of yellow atrophy of the liver with autopsy findings. Fitzgibbon and Silver,⁷ in a series of 200 cases showing toxic

*From the Medical Department, Mount Sinai Hospital, Cleveland.
Received for publication, December 16, 1939.

sulfanilamide effects, noted one severe nonfatal case of hepatitis. Fatal subacute atrophy of the liver with necropsy findings, however, is still sufficiently rare to warrant recording, this being only the second case to be reported in the English literature.

CASE REPORT

J. R., a white male, aged 67 years, was admitted to the surgical service of Mount Sinai Hospital on April 17, 1939, with the complaint of urinary frequency, hesitancy, and nocturia of five years' duration. He had had a similar attack ten years previous, but, following a cystoscopic examination, he seemingly improved for a period lasting five years. He had had pneumonia at the age of 12 years, and hay fever for the past four or five years. Physical examination revealed a few moist râles at both bases. His blood pressure was 180/90; examination of the abdomen gave negative findings; the prostate gland was hypertrophied, grade III. Laboratory data: phenolsulfonphthalein test was 70 per cent in three hours; blood chemistry was normal; Kline tests were negative; urine: albumin two plus; sugar (negative); blood count: innumerable red blood cells; hemoglobin 90 per cent, white blood cells 7,500. As part of preoperative treatment the patient was given on April 18, 10 grains of sulfanilamide three times a day for three days (total 100 grains) without any apparent untoward symptoms. Suprapubic prostatectomy was performed on April 22 under spinal anesthesia. Pathologic diagnosis: chronic and subacute prostatitis with nodular glandular hypertrophy and considerable hyperplasia. The patient made a good recovery and was discharged on May 10.

He was readmitted to the medical department on June 16, 1939. He stated that he felt well after leaving the hospital until about June 2, when he was given by his attending physician six 5-grain tablets of sulfanilamide daily for ten days (total of 20 Gm.) on account of pyuria. Soon after starting the drug he began to have anorexia, nausea, weakness, and began to pass "coffee-like" urine and light-colored stools. The patient blamed the medicine for his symptoms and stated that as soon as the drug was discontinued these symptoms subsided. Physical examination on this admission showed a considerable degree of jaundice, an enlarged liver palpable two fingerbreadths below the costal margin, and the edge of the spleen was palpable. There was no ascites, and there were no visible distended veins. The blood pressure was 136/84. Impression: toxic hepatitis probably due to sulfanilamide. (Dr. G., the family physician, reported that jaundice was not present on June 12, three days before admission.) Course: the jaundice increased rapidly. There was no urobilin or urobilinogen in the urine, and the stool was negative to hydrobilirubin except on July 10 and 15, when it was slightly positive. The jaundice was of the obstructive type, and it was our opinion, chiefly because of the enlarged spleen, that the patient had a toxic hepatitis merging into a chronic state, due to sulfanilamide. On July 12 signs of ascites, which progressively increased, were in evidence. On July 19 the patient was released at his own request. Laboratory examination during this admission was as follows: gastrointestinal series was negative; flat plate of the right upper quadrant was negative; electrocardiogram: P-R interval twenty-three seconds and slight slurring of QRS wave in limb leads; urine: bilirubin was positive in all specimens; urobilinogen negative; clumps of white blood cells; no leucine or tyrosine; blood: mild normocytic anemia, hemoglobin 75 to 76 per cent; white blood cells 5,700, red blood cells 3.8 million; icteric index varied between 90-67-115; van den Bergh test 19.2 units on June 17; cholesterol 210-203; esters 50 to 30; chemistry: nonprotein nitrogen 30, creatine 1.5; total plasma proteins 5.5; albumin 4.45; globulin 1.25; Kline test: diagnostic two plus, exclusion four plus on June 17 and June 19 (however, negative on first and on last admissions); stool hydrobilirubin was negative (eighteen examinations) except on July 10 and July 15, when it was slightly positive; ascitic fluid: no fixed tissue present; no cells. Pathologic report: fibrin clot. Treatment consisted of high carbohydrate diet supplemented by glucose and high vitamin diet and some bile salts, and paracentesis when indicated. Weight on admission was 163 pounds; on discharge, 163 pounds.

The patient was admitted to another service for paracentesis and peritonectomy on July 28. His diagnosis was cirrhosis of the liver.

The patient's fourth admission to the hospital and his second admission to the medical service occurred on August 4. At that time jaundice was intense, and ascites had increased. The liver edge was not felt and percussion showed it to be smaller than on the previous admission; the abdomen was distended with fluid. The course now was progressively and rapidly downward. On August 14 the patient began to get drowsy (cholemia); this drowsiness gradually merged into coma and he died on August 22, 1939.

Fig. 1.—Liver. Low-power magnification. Extensive necrosis with replacement fibrosis. ("Toxic hepatitis." "Subacute yellow atrophy.")

Fig. 2.—Liver. Low-power magnification. Extensive necrosis with replacement fibrosis. Beginning cirrhosis. ("Toxic cirrhosis.")

On this admission nonprotein nitrogen was 34, icteric index was 120, cholesterol 180, esters 27.5, total plasma proteins 4.65, albumin 2.32 and globulin 2.33. In the urine bilirubin was positive; urobilinogen was positive (hydrobilirubin, however, was negative on three examinations); leucine and tyrosine were negative. Blood count showed red blood cells 4 million, hemoglobin 75 per cent, white blood cells 8,000 to 12,000. Bleeding time was two minutes and clotting time was four minutes. Kline test was negative. Abdominal fluid was tapped and showed abundant growth of *Staphylococcus aureus* (contamination). The temperature

was normal throughout his hospital stay, except on admission (101.5 on June 16), on June 25 (100.5), and for a week following operation. Final diagnosis was subacute yellow atrophy of the liver and cholemin.

Permission for an autopsy was not obtained, but through a puncture wound we were able to obtain several small segments of liver tissue which form the basis of the pathological report submitted by our pathologists, Drs. B. S. Kline and A. M. Young, as follows:

Autopsy was limited. The liver is small, firm, and finely granular. On microscopic examination the liver cells in many places show early degenerative changes with some of the nuclei pyknotic and deeply blue stained, and others poorly stained or unstained with cell outlines blurred. In these areas there is abundant granular greenish-yellow bile pigment in the cytoplasm of the liver cells and homogeneous bile in the canaliculi. In other areas the liver cells are necrotic (see Fig. 1) and in many places they are absent, with apparent condensation of the stroma and bile ducts. Many of the small bile ducts are overdistended by homogeneous masses of bile. There is considerable infiltration in the periportal areas by wandering cells, with small round cells predominating (see Fig. 2). The normal lobulation of the liver is destroyed, the intact liver tissue occurring in irregular small rounded nodules characteristic of beginning cirrhosis. Anatomic diagnosis: extensive necrosis and replacement fibrosis, liver ("toxic hepatitis," "subacute yellow atrophy," and beginning cirrhosis, "toxic cirrhosis").

The patient apparently had a normal liver by the usual standards of examination, until he began to take sulfanilamide. No other drug was taken, and there is no history of previous contact with any hepatic irritants. He ingested 6.6 Gm. of sulfanilamide over a period of three days, April 18 to April 22, and again a second course of 20 Gm. over a period of ten days, June 2 to June 12. This was promptly followed by gastric upset, with nausea and vomiting, and about four days after the discontinuance of the drug he developed jaundice, enlarged liver and spleen, and later ascites. It is reasonable, if not certain, to accept a causal relationship between the drug and the hepatitis. Further, presumptive evidence may be had in the patient's own statement that gastric disturbance promptly followed the taking of the tablets, and promptly disappeared upon discontinuance of them. This case differs from the two fatal cases of hepatitis reported by Bannick, Brown, and Foster⁴ in that they believed that their patients might possibly have suffered from pre-existing liver damage; it differs also from Garvin's⁵ fatal case, in which hepatitis was complicated by exfoliative dermatitis and anemia. There were no skin lesions and no appreciable anemia in our case, and, as stated before, no evidence of previous liver damage. The Kline test was completely negative at first, then positive (diagnostic two plus, exclusion four plus), and again completely negative, and there was nothing in the history or physical examination to support the suspicion of a syphilitic involvement. Because of the age of the patient (67) and the painless progressive jaundice of the obstructive type, the possibility of malignancy suggested itself. However, the enlarged spleen, which was readily palpable on the first admission, made the differential diagnosis in favor of hepatitis and cirrhosis, and finally subacute atrophy (necrosis) of the liver. This impression was supported by a definite history of sulfanilamide ingestion, the absence of malignant cells from the ascitic fluid, the negative peritoneoscopic examination as regards tumors, the interruption in

the complete obstruction, as evidenced by the occasional finding of hydrobilirubin in the stool and urobilinogen in the urine, plus the subsequent decrease in size of the liver.

It is of interest to note that Saphirstein's² patient had an associated exfoliative dermatitis, and so did three of Garvin's⁵ series of five patients, and that the only fatality was one of these patients. Our own patient was apparently free from all skin lesions during his present illness; so was the one of Cline⁶ and of Fitzgibbon and Silver.⁷

This, then, is the second case of sulfanilamide hepatitis with post-mortem findings of the liver to be reported. With the increasing use of this drug more cases of hepatitis are to be expected. Whether this injury is due to hypersensitivity or to inherent toxicity, it is difficult to say. The case of Fitzgibbon and Silver⁷ suggests the former. After an interval of six weeks following the last dose of sulfanilamide, their patient took 15 grains (1 Gm.) more of this drug and six days later developed severe hepatitis. Similarly, in our case there was an interval of about six weeks between the two courses of the drug, and the appearance of jaundice occurred within four days after its discontinuance. Also, in 7 of 32 patients of Bannick and associates⁴ the previous administration of sulfanilamide rendered further treatment with this agent inadvisable. Recently, one of us (H. S. A.) had a similar experience with sulfapyridine. Repeating the drug after an interval of seven days brought on such severe gastric disturbance that it necessitated prompt discontinuance of the sulfapyridine, bringing prompt relief of the symptoms. Some of the patients may eventually overcome these toxic effects with the continuance of the drug, but it is a much safer procedure to discontinue it.

On the other hand, Hageman and Blake's¹ researches failed to demonstrate any precipitins for sulfanilamide in the blood serum during and following the reaction, as have attempts to demonstrate sensitivity by the patch and intradermal tests. Passive sensitization in human beings and in guinea pigs have also yielded negative results. Attempts to produce anaphylactic and skin hypersensitivity in guinea pigs have likewise failed. The prevailing view (Silver and Elliott,¹⁰ Garvin,⁵ and others) at present is that the sensitization phenomena are similar to those which occur with arsphenamine, einchophen, and aminopyrine.

There was a history of hay fever in our patient of about four to five years' duration. However, there was no opportunity for investigation of this angle, and no further enlightenment could be obtained from the family physician on this point. Its presence would have raised more than mere speculation as to the possibility of an allergic basis for the hepatitis following the second course of sulfanilamide therapy.

Apparently the dosage of sulfanilamide is not the only factor in its toxicity. Clark⁹ reports a patient who had taken 290 grains (18.85 Gm.) of sulfanilamide orally at one time "with no more serious effects than a transient decrease in the respiratory rate and a marked drowsiness, both of which symptoms were entirely relieved within twenty-four hours by forced fluids and respiratory stimulants." Cline's patient⁶ who died received 45 Gm. of sulfanil-

amide and the one of Fitzgibbon and Silver⁷ 500 grains (33.3 Gm.) of sulfanilamide. Our patient received the smallest amount, a total of 26.6 Gm. of the drug. While there is an accepted general plan of dosage, each case is an individual problem as to how much sulfanilamide it should receive. Long's studies indicate the value of a concentration of 10 to 15 mg. of the drug per 100 c.c. of blood in the fulminating cases, and from 5 to 10 mg. per 100 c.c. of the blood as a favorable concentration to obtain good results in the mild and moderate cases.

SUMMARY

We have presented a case of fatal hepatitis (subacute yellow atrophy of the liver) following the ingestion of 26.6 Gm. of sulfanilamide, and have presented the post-mortem findings of sections of the liver. This experience confirms the view of Garvin and others that sulfanilamide should be added to the list of agents which may cause severe damage to the liver, and further emphasizes the fact that it may even prove fatal. The danger of the indiscriminate use of sulfanilamide thus becomes obvious.

TRANSIENT POSITIVE SEROLOGIC TESTS FOR SYPHILIS*

ROBERT A. GREENE, PH.D., AND EDWARD L. BREAZEALE, B.S.A.
TUCSON, ARIZ.

IT IS generally recognized that syphilitic sera, upon storage, may gradually decrease in potency. As a general rule, these changes are fairly slow. It is common practice among smaller laboratories to hold positive sera for several weeks for use as controls in the performance of serologic tests.

In connection with an exchange of sera with other laboratories, we frequently noted that some which gave positive reactions in one laboratory gave negative reactions in others within a relatively short time interval. In other cases, the potency of sera remained practically unchanged over a period of time. Since the changes occurred chiefly in weakly positive sera, we attributed these changes to a decrease in reagent content. In weakly positive sera variations in sensitivity of antigens would be most pronounced.

The following event called our attention to the fact that changes may be even more pronounced. A young Mexican girl had applied for admission to a hospital for tubercular children. A blood specimen gave positive Kline, Hinton, and Kahn reactions. A second specimen gave negative reactions. A third specimen, which was divided, gave positive Kline, Hinton, and Kahn reactions in this laboratory, and negative Kahn and Wassermann reactions in another laboratory. The serum remaining from our tests was immediately referred to two other laboratories; one reported a negative Kahn reaction, the other negative Kline and Kahn reactions. The serum was returned to us, and upon re-examination gave negative Kline, Kahn, and Hinton reactions.

A fourth specimen gave negative reactions. A fifth specimen was examined separately so as to eliminate any possibility of mixing with other specimens. The specimen gave a positive Hinton, and strongly positive Kahn and Kline tests. The negative and positive controls gave negative and positive reactions, respectively. The serum and the controls were referred to two other laboratories; one reported a negative Kahn reaction, the other negative Kline and Kahn reactions. Both reported the negative control as negative and the positive control as positive. The serum was returned to this laboratory and re-examined. The serum gave negative Kline, Hinton, and Kahn reactions; the negative and positive controls gave negative and positive reactions, respectively.

The total time elapsing between our first and second examinations was less than three hours. The same lots of Kline antigen emulsion and Hinton glycerinated indicator were employed. The following day the serum was heated for ten minutes at 56° C. water bath and re-examined. The Kline, Kahn, and Hinton reactions were negative.

*From the Arizona State Laboratory, Tucson.
Received for publication, December 18, 1939.

As a result of this experience we decided to re-examine a number of sera on the day following examination. Our routine procedure has been to separate the sera, inactivate them for thirty minutes at 56° C. in an electrically controlled water bath, allow them to cool to room temperature, and then examine them immediately. When sera had been stored in the icobox, they were reheated for ten minutes in a 56° C. water bath before examination. In every case, the same lots of Hinton indicator and Kline antigen emulsion were used.

RESULTS

Several hundred sera have been examined in the manner just outlined. A large number of weakly reacting sera were negative upon recheck; as a general rule, strongly positive sera retained their potency over rather long periods of time. To date, we have not encountered a serum which gave negative reactions on the first test and positive reactions upon recheck. The results in Table I are representative of a large number of similar observations.

TABLE I

DISCUSSION

Although most of the sera which rapidly dropped in titer gave weakly positive reactions, a much larger number of weakly reacting sera continued to give weak reactions over a period of time. On the other hand, the occurrence of strongly positive reactions, which become negative within a few hours, presents a problem. At first, we felt that this might be a method of eliminating "nonspecific" reactions. During this study we have found, however, that in some cases, sera from known syphilitics might change from positive to negative, and reacting sera from individuals who were proved to be nonsyphilitic might retain their potency; in other cases, the situation might be reversed.

The simplest explanation would be that of poor performance of the laboratory tests. However, our branch laboratory at Phoenix made a very satisfactory record in the 1939 Evaluation Study, and an interlaboratory check over a long period has shown that the tests performed in the Tucson laboratory fall well within recommended limits of sensitivity and specificity.

The possibility of daily variation in sensitivity of the tests does not seem to be an adequate explanation. The same suspensions of Kline antigen emulsion and Hinton glycerinated indicator used in the first test were employed in subsequent examinations of the same serum. In a single series many specimens which gave weakly or strongly positive reactions on the first test, gave identical reactions upon re-examination at a later date. In no case did a negative serum give a positive reaction upon recheck.

SUMMARY

It was found that certain sera which gave positive Kline, Hinton, and Kahn tests, gave negative reactions when re-examined in a relatively short period of time.

AN EVALUATION OF THE COMBINED EFFECTS OF SULFAPYRIDINE AND THE BARBITURATES IN THE TREATMENT OF PNEUMONIA*

WILLIAM L. M. KING, M.D., AND HERMAN J. MOERSCH, M.D.
ROCHESTER, MINN.

BECAUSE of a report by Adriani¹ of New York in July, 1939, to the effect that rats placed under treatment with sulfanilamide were thereby rendered highly susceptible to the action of the barbiturates, we undertook this study. Adriani demonstrated that in rats so treated and then administered the sodium salts of methyl-butyl-ethyl-thiobarbituric acid (pentothal), isoamyl-ethyl-thiobarbiturate (thio-ethamyl), N-methyl-cyclo-hexenyl-methyl-barbituric acid (evipal), isoamyl-ethyl-barbituric acid (amytal), or methyl-butyl-ethyl-barbituric acid (nembutal), subanesthetic doses of these agents became anesthetic, and anesthetic doses of the same agents usually became lethal. The various anesthetic inhalants, such as ether and cyclopropane, on the other hand, did not have this effect on the sulfanilamide-treated rats, nor did tribrom-ethanol. The dose of sulfanilamide given the rats was from 0.5 to 1.0 mg. per gram of body weight daily for three days. Adriani concluded his report by suggesting that the combination of sulfanilamide and barbiturates may be unwise in human therapy.

We have reviewed 18 cases of primary pneumonia to determine whether the customary use of barbiturates as sedatives in conjunction with sulfapyridine had produced any recognizable deleterious effects. In one case the clinical diagnosis was pneumonia and the Neufeld reaction was positive, but the results of two roentgenologic examinations of the thorax were negative. This case was included because both sulfapyridine and pentobarbital sodium had been used during treatment of the patient.

We have presented in Table I the respective total doses of sulfapyridine or sulfanilamide and the particular barbiturate used in each case, together with the patient's age, the result of typing his sputum, and a short comment on the

45 yr.	Negative	150	9.7					6	0.4						No ill effects; died of hypertensive cardiac failure; secondary cardiac arrest
70 yr.	Negative	255	16.5	160	10.1	3	0.2	3	0.2						March 1922; recovered

course of his illness and the complications, if any. It will be seen that the most frequently used barbiturate was pentobarbital sodium and that the dose of sulfapyridine in the adult patients averaged approximately 330 grains (21.4 Gm.). The ages of the patients ranged from 3 months to 92 years. The Neufeld reaction was positive for a specific type of pneumococcus in 7 of the 18 cases. In a careful analysis of the hospital records, we were unable to find any suggestion that an untoward reaction that might be attributed to a combined effect of the two types of drugs had occurred in any of the cases, save one. This was true irrespective of the age of the patient, the type of pneumonia from which he was suffering, or the presence of complicating factors, such as pleural effusion or parotitis.

The one exception involved was a woman aged 27 years, who was in her seventh month of pregnancy and who had a lobar type of pneumonia involving the left lower lobe caused by pneumococcus type XII. The day after her admission to the hospital, her temperature decreased from 103.6° F. (39.8°C.) to normal, but on the third day she began to go into labor. Six grains (0.4 Gm.) of sodium amytal and $\frac{1}{200}$ grain (0.00032 Gm.) of hyoseine were administered and she went into a deep sleep from which she could not be roused for eighteen hours. The total dosage of sulfapyridine administered up to that time was 225 grains (approximately 14.6 Gm.). The onset of labor was delayed thirteen days.

SUMMARY AND CONCLUSIONS

We have studied 18 cases in which primary lobar pneumonia or bronchopneumonia has been treated with sulfapyridine or sulfanilamide and in which the patient was given one or more of the barbiturates in sedative doses. No untoward effects were observed, except in one instance in which prolonged stupor of the patient followed the administration of 6 grains (0.4 Gm.) of sodium amytal following a previous dosage of 225 grains (approximately 14.6 Gm.) of sulfapyridine. That this reaction was the result of the combined effect of the two drugs can be postulated, but the postulation would be difficult to prove.

It may be concluded, therefore, that the barbiturates in ordinary sedative doses may be used with apparent immunity for patients receiving sulfapyridine or sulfanilamide.

CLEARANCE TESTS IN RELATION TO RENAL PATHOLOGY*

ESTHER M. GREISHEIMER, ROBERTA HAFKESBRING, AND HULDA MAGALHAES
PHILADELPHIA, PA.

FOR some time we have been studying the effects of various anesthetics on kidney function. In this report the results of 275 urea clearance tests and 106 creatinine clearance tests on 10 dogs are presented. The following range of control values of urea clearance per square meter per minute has been noted: Orth,¹ 34.9 c.c.; Rhoads,² 49.8; and Ralli,³ 99.5. Because of this great variation and the inconstant results in some of our dogs under anesthesia, it seemed advisable to do autopsies at the end of our study. We are deeply indebted to Professor Helen Ingleby and her staff for autopsy reports on 7 of our dogs. Although complete autopsies were performed, only the kidney findings will be included in this paper.

On each experimental day, body weight, blood pressure (Allen⁴), respiratory rate, heart rate, rectal temperature, erythrocyte and leucocyte counts, and hemoglobin (Newcomer method) were determined. The average control values for each dog are shown in Table I. Urea clearances were done by the Van Slyke⁵ hypobromite method; creatinine clearances were done by the Holten and Rehberg⁶ method. Adult female dogs, in reasonably good health and well trained, were used. They were allowed to lie comfortably between catheterizations on the laboratory floor on blankets. Tests were done eighteen to twenty-one hours after the last meal, and no more than two tests were done on one dog in one week. The dogs were permitted to exercise daily on the roof. Some of the dogs were studied for as long as sixteen months before coming to autopsy.

Some of the dogs were fed Red Heart C, some Victory Dog Food, and the remainder Cero-Meato. Three dogs were studied for several months on each of the diets in turn, and no significant changes in urea clearance were found. We noticed that all the dogs gained weight on Cero-Meato; the pathologist stated that the dogs which had been fed Cero-Meato seemed to be in better general condition at the time of autopsy than the dogs which had been fed either of the other diets.

A brief report of the results of each anesthetic will be given. In each anesthetic period surgical anesthesia was maintained for one hour. The clearance tests on the day after the anesthesia were compared with those before and with those one, two, and more weeks after.

*The heart rate was determined from the electrocardiogram instead of by stethoscope.

(a) Cyclopropane* (Diet—Red Heart C)

1. Dog R. During eight months cyclopropane was administered ten times, and the dog seemed in excellent health throughout. The most significant finding was the increase of about 40 per cent in the urea clearance on the day after the anesthesia; this was noted each time cyclopropane was administered. The average control value was 56.2 c.c. per square meter per minute, as shown in Table I, and the average value for the day after anesthesia was 79.5; this finding does not agree with that of Orth.¹ The urea clearance returned to the control value within one week after the anesthesia.

After 42 clearance tests and ten administrations of cyclopropane this dog was brought to autopsy by a lethal dose of the same anesthetic. The kidneys showed congestion only; consequently, we feel that these results are typical of cyclopropane.

2. Dog N. It may be noted in Table I that this dog showed a higher blood urea nitrogen than any of the others, and it was the only one with hypertension. It showed a rather fixed urea clearance in the 11 tests performed. Cyclopropane was administered only three times, since the dog died just at the end of the third period. The control value for urea clearance was 54.9; after the anesthesia it was 54.3.

At autopsy the kidneys showed capillary engorgement of the glomeruli and cloudy swelling of the tubules. This pathology, together with the hypertension and higher blood urea nitrogen, probably was a determining factor in the fixed clearance.

3. Dog W. Thirteen clearance tests were done on this dog. The average control value was 55.5; after one administration of cyclopropane it increased

*We are greatly indebted to the Foregger Company for the generous loan of the Foregger instrument, Metric Model No. 4, for administration of cyclopropane.

to 66.7, or about 20 per cent. Since this dog was not able to be trained to our satisfaction, it was returned to the kennels.

(b) Pentobarbital sodium (Abbott) (Diet—Victory Dog Food)

Twenty-two anesthetic periods were studied on Dogs C, D, and F. The following results were found for urea clearance:

DOG	CONTROL	AFTER ANESTHESIA
C	61.0	55.2
D	40.5	44.7
F	59.9	69.0

Since comparable results were found at some time during the establishing of the control values in two of the dogs, we felt that there were no significant changes which could be attributed to the anesthesia.

(c) Sedative dose of pentobarbital sodium followed by ether, drop method, for one hour (Diet—Red Heart C)

Dogs C, D, and F were left in the kennels for the summer and were studied again in the autumn. After new controls were established, each dog was given ether once. The following results were found:

DOG	NEW CONTROL	AFTER ANESTHESIA
C	56.7	72.2
D	47.0	49.9
F	64.8	86.7

The urea clearance increased markedly in two and only slightly in one the day after ether was administered. Orth¹ reported practically no change after ether. The urea clearance tended to return to the control value within one week.

The diet was changed to Cero-Meato at this time. After allowing about one month for complete recovery from ether and for adjustment to the new diet, new controls were established and additional studies were made. Creatinine clearances were begun and the two clearance tests were done simultaneously. According to Jolliffe,⁸ the administration of creatinine does not affect the rate of urea excretion.

(d) Sodium amytal (Diet—Cero-Meato)

Eighteen periods of anesthesia on Dogs C, D, K, and L were observed. The following results were found:

DOG	UREA CLEARANCE		CREATININE CLEARANCE	
	CONTROL	AFTER ANESTHESIA	CONTROL	AFTER ANESTHESIA
C	68.9	68.9	75.9	91.3
D	50.4	62.5	59.5	69.3
K	64.3	72.9	75.8	107.8
L	71.3	49.8	74.3	86.7

As noted, the urea clearance did not show a constant change. The creatinine clearance increased in every case. The autopsy reports on these dogs are instructive.

1. Dog C was brought to autopsy after having had 52 urea clearance and 20 creatinine clearance tests. The glomeruli of the left kidney showed a thickening of the basement membranes of the capillaries, Bowman's capsules, and afferent arterioles. Many of these arterioles were dilated and the walls thickened where they entered the glomerular tuft. The basement membrane of the tubules was slightly thickened. There were thin-walled spaces lined by endothelium and containing blood scattered throughout the kidney substance and pelvis.

The right kidney showed intense congestion and hemorrhage. There was a triangular area infiltrated with mononuclear cells beneath the capsule. This area was partly fibrosed. The afferent arterioles and basement membranes were less affected than in the left kidney, but inflammatory lesions were more prominent. The diagnosis was interstitial nephritis and nephrosclerosis.

This dog showed relatively high clearances in spite of the renal pathology, but the variations after anesthesia were less marked than in some of the other dogs.

2. Dog D was brought to autopsy after 54 urea clearance and 27 creatinine clearance tests. The only report on the kidneys recorded by the pathologist was that the glomeruli were intensely congested and there was slight cloudy swelling of the tubules.

3. Dog K was brought to autopsy after 19 urea clearance and 18 creatinine clearance tests. The blood vessels in the interstitial tissue and some glomeruli were congested. There was a slight thickening of the basement membrane of the capillaries of the glomeruli and also a thickening and dilatation of some of the afferent arterioles. Many Bowman's capsules were thickened, and in some areas the capsules were enormously distended with granular material. These glomeruli resembled those seen in lipid nephrosis in human kidneys. Cloudy swelling of the convoluted tubules was noted.

This dog had a high white blood cell count, as shown in Table I, and gave very irregular clearance tests, as might be expected in view of the renal pathology.

4. Dog L was brought to autopsy after 7 urea clearance and 7 creatinine clearance tests. The kidneys were intensely congested. The glomerular capillaries were enormously distended, with an occasional hemorrhage into the capsule. The appearance of some of the glomeruli suggested a hemorrhagic nephritis. The clearances were irregular in this dog.

(e) Sodium barbital (Diet—Cero-Meato)

Dogs M and F were used, and only four periods of anesthesia were observed. The following results were found:

DOG	UREA CLEARANCE		CREATININE CLEARANCE	
	CONTROL	AFTER ANESTHESIA	CONTROL	AFTER ANESTHESIA
M	59.5	61.8	77.1	53.1
F	60.6	46.5	58.8	85.5

As noted, the results were very irregular. Dog M, after 10 clearance tests, was used for other purposes and did not come to autopsy.

Dog F had been used for 59 urea clearance and 24 creatinine clearance tests before coming to autopsy. The kidneys showed congestion. In many glomeruli there was extreme dilatation of the afferent arterioles and the capillaries. Hemorrhage was evident in some of Bowman's capsules.

Dog B was used only for 8 control urea clearance tests. Since the range was from 35.7 to 132.3, it was used for other purposes and was not brought to autopsy.

SUMMARY AND CONCLUSIONS

1. The urea clearance increased as much as 40 per cent on the day following the administration of cyclopropane and returned to normal within a week in a dog with no renal pathology. In a dog with hypertension, high blood urea nitrogen, and some renal pathology, a fixed urea clearance was found.

2. The administration of pentobarbital sodium (Abbott) failed to produce greater changes in the urea clearance than were found in the normal range of two of the dogs.

3. The administration of ether (drop method) after a sedative dose of pentobarbital sodium was followed by a marked increase in the urea clearance in two dogs and a very slight increase in a third dog.

4. The administration of sodium amytal was followed by an increase in the urea clearance in one dog with little renal pathology; the results were inconstant in three dogs with considerable renal pathology. The creatinine clearance increased in every case; there was great variation in the amount of increase.

5. The administration of sodium barbital was followed by a decrease in the urea clearance and an increase in the creatinine clearance in one dog with some renal pathology.

6. High leucocyte counts, elevation of rectal temperature, and renal pathology seem to be associated with inconstant urea clearance.

7. The inconstancy of urea clearance results has been noted by Goldring,⁸ Holman,¹⁰ and Van Slyke.¹¹ We consider it worth while to follow a series of clearance tests on one animal by autopsy.

8. It is possible that sedation with barbiturates on the night preceding a clearance test may influence the results. An elevation of temperature and a high leucocyte count may likewise affect the results.

INCIDENCE OF BACTERIEMIA IN PATIENTS WITH DENTAL DISEASE*

MAYNARD MURRAY, M.D., AND FRANK MOOSNICK, B.S.
CINCINNATI, OHIO

FROM clinical observation one is aware of the fact that bacteriemia must occur frequently without peripheral manifestations of sufficient grade to say the patient is "diseased." Proof may be seen in the fact that traumatized tissues in which abrasion of the skin was absent are frequently infected. Thus hematomas that come up infected or the osteomyelitis that follow slight trauma may be taken as good evidence that a bacteriemia existed and that an infecting organism reached the point of infection through the blood stream. As promulgated by Rosenow¹ and Fischer,² the teeth act as chronic foci, are a common source of invasion of the blood stream, and hence are responsible for the diseased processes that occur in distant lying tissues.

If the view of these authors is correct, one should expect to be able to uncover the existence of bacteriemias in patients affected with chronic dental disease. Okell and Elliot³ found a transitory bacteriemia in from 60 to 70 per cent of their patients after the extraction of teeth under general anesthesia; Burket and Burn,⁴ in 17 per cent of their patients when local anesthesia only was employed. The latter explained their low incidence by saying that the suprarenin employed acted as a vasoconstrictor to render the vessels less permeable to the entrance of microorganisms.

To learn how frequently bacteriemia occurs in dentally affected patients not subjected to operation, the following experiment was performed: Three hundred and thirty-six patients with varying degrees of dental caries and pyorrhea were asked to chew a 1 inch cube of high melting point paraffin. After chewing this for one-half hour, blood cultures were taken from the femoral artery.⁵ (The area was scrubbed with tincture of green soap and water, followed by iodine and alcohol, and then the application of tincture of merthiolate. Cultures from skin areas so treated were routinely negative.) The blood withdrawn from the artery was mixed with brain broth containing one-half of 1

Received for publication, December 28, 1939.

per cent peptone, and allowed to stand for six days at 37° C. Thereafter subcultures were prepared in heart infusion agar.

These blood cultures proved positive immediately after chewing in 153 or 55 per cent, of the patients studied. Follow-up blood cultures were not taken to determine how long such a bacteremia might persist.

The organisms found were a small diplococcus in 84 per cent of the positive cultures and a slowly growing *Staphylococcus albus* in the remaining 16 per cent. One patient displayed both organisms. Subclassification was not completed.

SUMMARY

Of 336 patients with dental disease, 185 gave positive arterial blood cultures after they had chewed paraffin for one-half hour.

THE HISTAMINE TREATMENT OF ALLERGIC DISEASES*

I. ASTHMA AND VASOMOTOR RHINITIS

LAURENCE FARMER, M.D., NEW YORK, N. Y.

NUMEROUS observations have led to the assumption that the symptoms of experimental anaphylaxis and of clinical allergy are caused by histamine or a histamine-like substance. Dale's¹ theory of anaphylaxis presupposes that the combining of antigen and antibody in sensitized tissues leads to cell lesion and the liberation of preformed histamine or of a histamine-like substance. Lewis and his collaborators Grant and Hare^{2, 3} expanded this theory to explain the "anaphylactic" skin reactions in allergic human beings. In certain individuals heat, cold, or mechanical irritation, in degrees perfectly tolerated by normal persons, causes cell lesion and the liberation of histamine from the tissues (Duke, Bray, Horton⁴). The clinical manifestations of these "physical" allergies are usually the same as those in the "atopic" allergies.

Fuehner⁵ was the first to show that it is possible to induce refractoriness to histamine in normal animals. This phenomenon was observed in normal human beings by Lewis and Grant.⁶ Hare showed in allergic persons that "the histamine stimulus renders the skin refractory to the anaphylactic poison."

*From the Allergy Clinic, Lenox Hill Hospital, New York.
Received for publication, January 2, 1940.

Nonspecific "desensitization" with histamine was achieved by Farmer,⁷ who was able to induce diminished sensitiveness to serum in serum-sensitized guinea pigs through oral and parenteral application of histamine.

The theoretical and practical implications of these observations for the understanding and treatment of allergic diseases are obvious. The histamine theory would explain why the symptoms of allergic conditions are independent of the nature of the causative allergen, and dependent only on the reaction of the shock organs. The possibility of achieving refractoriness to histamine would reduce the treatment of allergic diseases to a common denominator and thereby make for much simplification. It would, furthermore, be very useful in all those cases of multiple sensitiveness in which several allergens would have to be used for specific desensitization, and also in those cases in which the causative allergen or allergens could not be discovered.

Histamine was first used in the treatment of an allergic condition by Ramirez and St. George⁸ in 1924. These authors had observed a group of patients with what they termed "endogenous" asthma. The patients who did not as a rule react to the various proteins tested⁹ but gave "an exceptionally strong reaction with solutions of histamine," were suffering, according to Ramirez and St. George, from "histamine sensitivity." Ten patients were treated with subcutaneous injections of histamine in doses ranging from 30 to 750 gamma; very good results were achieved in two patients.

The cases of Ramirez and St. George fit neither into the category of "atopic" nor into "physical" allergy. Recently Horton⁹ has described a syndrome, which he calls "erythromelalgia of the head" (vascular headache), and which he attributes to histamine. Relief of the symptoms in these cases was also achieved by histamine injections. It is possible that the cases of Horton belong to the same category as those of Ramirez and St. George.

In 1927 Friedlaender and Petow¹⁰ reported that they had used histamine in the treatment of migraine of various origins. Ernestene and Banks,¹¹ Gajdos,¹² and Joltrain¹³ treated urticaria with histamine; and Collens and his collaborators¹⁴ used it successfully in a diabetic person who had developed insulin sensitivity.

The reports on the use of histamine in bronchial asthma are few and far apart. In 1932 Stahl and Masson¹⁵ in Strasbourg, and two years later Piquet,¹⁶ Stahl's pupil, treated asthmatic attacks by applying histamine to skin scarifications. In 1935 Thiberge¹⁷ in this country, and Dszinich¹⁸ in Hungary reported on the treatment of asthma with injections of histamine. Thiberge used large doses of histamine: 0.5 c.c. of a 1:1,000 solution per injection. Dszinich used much smaller amounts, his initial doses in severe cases being 0.01 gamma, and in milder cases 0.1 gamma (0.00001 mg. and 0.0001 mg., respectively). Jacquelin¹⁹ in 1937 stated that he had applied histamine by iontophoresis in a few cases of asthma. Openchowski²⁰ mentioned having used histamine in asthma and other allergic conditions, but he does not give any details. All these authors were impressed by the results they achieved.

In view of these favorable clinical reports and of the afore-mentioned theoretical considerations, we felt that the use of histamine in allergic diseases

could be of essential value. It was necessary to investigate further the question of dosage and of appropriate mode of application. We felt that injection would be preferable to scarification or iontophoresis, as neither of these latter methods allows accurate dosage. However, we believed that the smaller amounts of histamine which were used in these methods, and which were also recommended by Dzsinič, would give better therapeutic results than the larger doses used by the earlier workers.

We have been using subcutaneous injections of histamine phosphate* in the treatment of various allergic diseases for three years. No hard and fast schedule of dosage has been developed. Following the suggestion of Dzsinič, the initial dose in mild cases of asthma is 0.1 gamma, and in more severe cases it is 0.01 gamma. The injections are increased each time by 50 per cent, if well tolerated, and in the beginning they are given two to three times weekly. They are later spaced at approximately five-, seven-, ten-, fourteen-, and twenty-one-day intervals. The rapidity with which the dose is increased and the spacing of the injections will depend upon the patient's tolerance and the results achieved. The maximum dose has been 50 to 75 gamma. However, in most instances very satisfactory therapeutic results have been achieved with much smaller amounts of histamine. If an injection is not well tolerated, or if a marked local reaction occurs, a smaller amount should be given the next time. In some instances, after marked improvement had been achieved in the course of treatment, the patient's condition gradually became worse. Since we felt that the patients were possibly getting too much histamine, we decreased the amount injected, and the patients again improved. In a number of cases even such small amounts of histamine as 0.03 to 0.07 gamma have caused marked exacerbation of the asthmatic attacks. It was necessary to reduce the injections to 0.005 gamma and to increase the doses very slowly. There is no method of ascertaining the amount of histamine needed in each individual case other than following the clinical course.

As in specific desensitization, histamine injections should be continued over a considerable period of time, especially if the therapeutic results are good. We have found it advisable to give a second or third series of injections after a pause of several months, even in the absence of symptoms.

We have given several thousand individual injections of histamine and have encountered a systemic reaction in only two instances. In the one case, after the injection of 1.0 gamma, the patient who was suffering from vasomotor rhinitis developed severe urticaria, which started at the site of the injection and spread over the entire body. The urticaria persisted for several days. In the other case the patient developed angioneurotic edema of the eyelids on several occasions after the injection of small amounts of histamine.

The precautions to be taken are the same as in specific desensitization. The injections should not be given into a venule or capillary, adrenalin and a tourniquet should always be on hand, and the patient should be observed for ten to fifteen minutes after the injection. However, we believe that histamine treatment causes systemic reactions less frequently than specific desensitization.

*Parke-Davis & Co. product.

We have treated with histamine 54 patients suffering from asthma, vasomotor rhinitis, or both, whose symptoms were in most instances due to allergens other than pollens. (We intend reporting on the pollen-sensitive patients in another paper.) Table I contains data on only 23 of the 54 patients. These patients were observed sufficiently long to allow conclusive evaluation of the effectiveness of histamine treatment.

All patients received physical and x-ray examinations, a routine urine examination, and a complete blood count; skin tests were carried out with the most important foodstuffs and inhalants. In almost all cases the patient was also examined otolaryngologically. As shown in Table I, the majority of the patients gave positive skin reactions to one or more allergens. These allergens were eliminated if possible, and the patient received histamine if the elimination did not lead to the desired therapeutic result.

CASE REPORTS

The following three case histories, which we present in detail, are illustrative of successfully treated patients:

CASE 3.—F. L. is a 36-year-old baker who has been suffering from severe vasomotor rhinitis for three years. His attacks of paroxysmal sneezing and profuse watery nasal discharge come on only in the bakeshop and only when working with wheat flour. They commence after he has been in the bakeshop for one to two hours, and last for many hours. His personal and familial histories are not contributory. Two years before he visited us he had a tonsillectomy; one and one-half year before, a resection of nasal septum with some improvement. X-ray of the chest and blood count were normal. Intradermal skin test with wheat extract was strongly positive. Histamine treatment was started with 0.1 gamma on Feb. 21, 1938. Decided improvement was noted after the eleventh injection, 3.0 gamma, on March 21. Improvement continued and the patient was able to work during April, May, and June without any symptoms of rhinitis. He was receiving injections of histamine during this time. The last injection of 40 gamma was given on July 6. The patient came back to the clinic on Sept. 21, 1938. He had been working during the summer and had had only infrequent, very mild symptoms. During the week prior to his readmission he had been sneezing more frequently. He was given four injections of histamine, and then did not return to the clinic as he was again feeling better. On July 28, 1939, he reported that he had been steadily working with wheat flour since Nov. 1, 1938, and that he had had no symptoms of rhinitis.

CASE 18.—H. V., a 7-year-old boy, has been suffering from rhinitis for three years and from bronchial asthma for one and a half years. His first attack of asthma occurred two weeks after tonsillectomy and adenoidectomy. The attacks come during the day and night, without any seasonal incidence. His mother has had eczema for eight years. Physical examination was negative; x-ray examination of the chest revealed slightly emphysematous lungs; differential blood count: 7 per cent eosinophiles; skin tests: house dust ++, feathers +++, rabbit dander +. Elimination of feathers from the child's environment brought no relief of symptoms. On Jan. 20, 1939, he was given his first injection of histamine, a 0.01 gamma dose. The allergic symptoms became milder soon after the beginning of treatment. Coughing and sneezing persisted longer than the asthmatic attacks. In April the patient had an attack of asthma which lasted for three days. At that time he was given 15 injections of histamine (highest dose was 1.0 gamma). There was very marked improvement by the end of May. The last injection (twenty-eighth), 4.0 gamma, was given on July 17, 1939. The child had no allergic symptoms at that time.

CASE 23.—H. W., a 50-year-old woman, has had severe asthma for thirty years. Several attempts at specific desensitization have aggravated her condition considerably. The last

treatment (injections of house dust and feather extracts) had been given eight years prior to her admission to the clinic. The patient's condition had been steadily becoming worse and she was giving herself injections of adrenalin two to three times daily. The physical examination was negative with the exception of wheezing breath sounds. The blood count was normal. Skin tests were negative. Urethane, 2 to 4 Gm. daily, was given symptomatically,²¹ with marked beneficial effect. The first injection of histamine (0.01 gamma) was given on Jan. 9, 1939. Under histamine treatment the patient's condition improved gradually. The attacks became less frequent and less severe. The patient was able to decrease the amount of adrenalin needed to stop the attacks. She had asthmatic attacks through January, but no attacks in February. By the beginning of March she had received 14 injections of histamine, the maximum dose at that time was 0.8 gamma. She had a moderately severe attack on March 3. There was occasional shortness of breath during March, but no real attacks of asthma. The patient from then on improved rapidly. Since she was planning to leave the city in June, the injections were given at twelve-day intervals during April, and at weekly intervals during May. She had no attacks during this time. The last injection (twenty-fifth), 3.0 gamma, was given on June 2. On August 17 she reported slight shortness of breath on two occasions since she was last seen. Her condition was very good and she needed no medication.

COMMENT

Our results with histamine treatment have been very encouraging, especially in a number of cases of asthma of long standing. One of the main problems still confronting us is the question of dosage. We feel that the earlier workers in this field were using too large amounts of histamine and that the dosage suggested by Dzsinich, which we used, is more appropriate.

We believe that some of our therapeutic observations, as for instance in the case of the wheat-sensitive baker, are a further proof of the correctness of the histamine theory of allergic conditions.

SUMMARY

1. The work of Dale and Lewis has laid the foundation for the theory that the symptoms of experimental anaphylaxis and of clinical allergy are due to the liberation of histamine or of a histamine-like substance in sensitive tissues.

2. Various authors have shown that it is possible to induce refractoriness to histamine in human beings and in laboratory animals. Furthermore, it has been demonstrated that it is possible to "desensitize" sensitized guinea pigs nonspecifically by injections of histamine.

3. These observations form the theoretical basis for the treatment of allergic diseases with histamine.

4. The technique of histamine treatment of asthma and vasomotor rhinitis is described, and the results of this treatment are discussed. The results have been very encouraging in a considerable number of instances and warrant further investigation.

INVESTIGATIONS ON THE RETICULO-ENDOTHELIAL FUNCTION OF CANCER PATIENTS

KURT STERN, M.D.,* NEW YORK, N. Y.

THE results of numerous experimental studies,¹ dealing with the role of the reticulo-endothelial system in cancer pathology, suggested to several research workers the possibility of their clinical application. Such investigations might prove of value in two ways: yielding an answer to the questions (a) whether or not a definite and regular involvement of the reticulo-endothelial system is associated with human neoplasia, and (b) if of a positive nature, this evaluation of the reticulo-endothelial function of cancer patients can be utilized for diagnostic and/or prognostic purposes.

Papers on this problem have been published by Krätschell,² Barbera,³ Kavetskiy,⁴ and Schroeder.⁵ All these authors stated on the basis of their work that a definite damage of the reticulo-endothelial function could be found in

*This work was carried out as Research Fellow of the New York City Cancer Hospital and subsequently as Postgraduate Student Observer of the New York University Medical School.

a high percentage of the tested cancer patients. The method generally used in these studies was the Congo red test proposed by Adler and Reimann.⁶ This test is based on the fact that Congo red, a colloidal dye, is stored after intravenous injection by the reticulo-endothelial cells. If, therefore, blood samples are withdrawn shortly after the intravenous injection and later after an interval of time, the concentration of the dye in the blood is found decreased in the second sample, thus permitting an estimate of the per cent of the dye which has been intercepted by the reticulo-endothelial system. The ratio between the dye concentrations in the two samples depends on the storing activity of the reticulo-endothelial system and is termed the Congo red index.

It must be admitted that objections have been raised against the usefulness of the Congo red test for an evaluation of the reticulo-endothelial function.^{7,8} But, on the other hand, animal experiments⁹⁻¹¹ definitely showed the direct connection of the functional activity of the reticulo-endothelial system and the Congo red test. Certainly the colloid-storing ability of this system is only one of its many functions, and it would be of great interest to include these in the clinical examination. But as these immunobiologic, metabolic, hormonal functions of complex character have not as yet been developed as generally applicable functional tests, the present available methods must be utilized. Besides Congo red, other colloids have been proposed for testing the storing capability of the reticulo-endothelial system,¹² but none of these methods appear to be superior to the Congo red test in simplicity and efficiency.

In previous investigations, in collaboration with Willheim,¹³ we applied the Congo red test to rabbits and worked out a modified method which (a) required only small amounts of blood (0.4 c.c. for the single sample, in contrast to the 10 to 20 c.c. of blood necessary in the original method), and (b) permitted a more exact colorimetry by transforming the Congo red into the acid, blue form. Later we published a similar modification¹⁴ which is applicable for clinical use and serves to the same advantage. The usefulness of these modifications has been confirmed by other authors who have used them in animal experiments¹⁵ and for clinical purposes.¹⁶

Because the original studies of the association of reticulo-endothelial function with cancer were carried out on a comparatively small number of cases—in about 50 patients for each experiment—and because we now have at our disposal a more reliable modification of the Congo red test which is also less disturbing to the patient, we were induced to resume the study of this problem and to apply this functional test of the reticulo-endothelial system to a larger group of cancer patients.

Method.—The original test, as well as our modification, is based on the following principle: 10 c.c. of 1 per cent watery Congo red solution are injected intravenously, four and sixty minutes, respectively, after the injection blood samples are withdrawn, and in the serum or plasma the Congo red concentration is colorimetrically determined. As the standard required for the colorimetry must contain the same amount of the patient's serum or plasma, another blood sample is first obtained immediately before the injection of the dye. While in the original method a rather primitive comparative estimation of the red color

of the samples was made, in our modification the Congo red is transformed into the blue compound by addition of hydrochloric acid, before which an acid buffer solution, containing urea, was added, thus (1) diminishing the acid-binding capacity of the serum proteins and (2) preventing their flocculation. Because of the low dye concentration in the samples (2 to 5 milligrams per cent, i.e., 20 to 50 γ in 1 c.c.), it was found necessary for exact colorimetry to add measured amounts of Congo red to the samples. By these procedures clear blue violet hues are obtained which can be easily colorimetrically compared and are proportional to the dye concentration as control experiments proved.

Solutions.—(1) A 1 per cent watery solution can be prepared by exactly weighing Congo red powder and sterilizing in the autoclave. This solution should be used within twenty-four hours and, therefore, must be freshly prepared. For the majority of our experiments we used Loeser's commercial preparation of "1 per cent Congo red."

(2) Sterile 3.8 per cent solution of sodium citrate.

(3) One-tenth per cent and 0.05 per cent Congo red solutions, freshly prepared by dilution of the 1 per cent Congo red solution, used for the injection in the same experiment.

(4) Glycine-hydrochloric acid buffer, containing 25 per cent urea. A mixture of 0.75 Gm. of glycine and 0.59 Gm. of sodium chloride are dissolved in 10 c.c. of water, and 52 parts of this solution are mixed with 48 parts of tenth-normal hydrochloric acid. In 100 c.c. of this mixture 25 Gm. of urea are dissolved. This reagent has a pH of approximately 2, and is usable for several weeks if stored in the icebox.

(5) Ten per cent hydrochloric acid.

Performance of the Test.—To avoid lipemia of the blood samples, the tested patient should be bled either after fasting or at least not shortly after the intake of food.

1. Using a dry 5 c.c. syringe or one rinsed with citrate solution, containing exactly 1 c.c. of 3.8 per cent sodium citrate, blood is aspirated from the cubital vein until the 5 c.c. mark (4 c.c. of blood). Aspiration of air bubbles must be avoided. The contents of the syringe are mixed and put into a dry centrifuging tube marked *Sample 1*.

2. Immediately following, while the needle remains in the vein, 10 c.c. of the 1 per cent Congo red solution are injected.

3. Four minutes after the injection blood is withdrawn in the same way as described above (*Sample 2*).

4. *Sample 3* is obtained sixty minutes after the injection.

Colorimetry.—All three samples are sharply centrifuged. After careful separation from the red blood cells, 2 c.c. of each sample are put into dry test tubes. To the colorless sample 1, serving as standard, 0.1 c.c. of the 0.1 per cent Congo red solution is added with a micropipette; to samples 2 and 3, 0.1 c.c. of the 0.05 per cent Congo red solution, corresponding to 100 and 50 γ , respectively, is added. To each sample is now added 2 c.c. of the buffer-urea solution and 0.5 c.c. of 10 per cent hydrochloric acid. Thus a blue violet color is

developed and the colorimetry is immediately performed, as precipitations may occur after longer delay. Sample 1, containing 100 γ Congo red, is used as standard.

Calculation.—The Congo red content of samples 2 and 3 is found by the equation $x = \frac{1000}{r} \gamma$, if the standard is kept at the mark 10 and r is substituted by the respective reading. From these values, 50 γ , which have been added as previously described, are subtracted for obtaining the originally present Congo red content of the samples. The Congo red index, showing the per cent of decrease of the Congo red and thus serving as measure of the reticulo-endothelial activity, is obtained by dividing the Congo red content of sample 3 by the Congo red content of sample 2 and multiplying this figure by 100.* The Congo red content of the samples, expressed in milligrams per cent, is found by dividing the γ values by 16.

*Congo red index.

Complications.—By strict attention to the above described procedure the plasmas obtained are never hemolytic. Should hemolysis occur, however, this source of error, so important in the original method, is easily detected as the acidification with hydrochloric acid results in a brownish color (hematin), which does not allow a colorimetric comparison. Such a test should be discarded. Strongly icteric or lipemic samples also might prevent a successful colorimetric determination. Finally, it is known that in amyloidosis intravenously injected

*Some authors, ourselves included, in reported animal experiments used a different Congo red index, figuring the per cent of decrease according to the formula: Congo red content of sample 2 minus Congo red content of sample 3 divided by Congo red content of sample 2 and multiplied by 100. This value corresponds to 100 minus the original Congo red index and is the higher, the more Congo red has disappeared.

Congo red disappears very quickly from the blood stream because of a great chemical affinity of Congo red to amyloid (Bennhold's test). In these cases, of course, the Congo red test cannot be used for an evaluation of the reticulo-endothelial function.

Using the described method, we tested 49 patients clinically free of malignancy, and 100 patients suffering from malignant neoplasms. In 12 cancer patients the test was repeatedly performed during and after radiation therapy. The results of these tests may be seen from Tables I to IV.

Table I, comprising the cancer-free patients, exhibits values of the Congo red index ranging from 32.7 to 73.9 per cent. Eight patients (11, 22, 25, 26, 29, 33, 41, 48) show indices near or beyond 70 and correspondingly must be considered as more or less impaired in their reticulo-endothelial function. The normal range varies between 30 and 65 per cent. In our experiments the average value is found as approximately 55 per cent, which means that a little less than half of the injected Congo red amount is stored by the reticulo-endothelial system during the time of the test.

Turning to the neoplastic cases it can be seen that 86 out of the 100 tested patients found in Table II exhibit values ranging between 70 and 100. In 14 cases, however, included in Table III, the Congo red index was found below 70.

On the basis of these results it seems possible to draw the following conclusions:

1. In 86 per cent of the investigated cancer cases a definite severe damage of the reticulo-endothelial function has been found by means of the Congo red test. This damage does not depend on a disturbance of the patient's general condition nor does it seem to be connected with the advancement or the generalization of the malignancy. While at present it cannot be explained why in 14 per cent of our cases this phenomenon could not be observed, the marked involvement of the reticulo-endothelial system in human neoplasia may be considered as an established and probably important factor of cancer pathology. For the time being, however, it cannot be decided if this phenomenon is primarily connected with tumor origin and growth or is only a secondary, concomitant factor. An answer to this question may be looked for from suitable animal experiments.¹⁷

2. A diagnostic value cannot be attributed to the Congo red test both because of its nonspecificity as many other conditions, mainly infections, also result in damaged reticulo-endothelial function, and because in about 14 per cent of our cancer patients the Congo red test failed to reveal an impairment of the reticulo-endothelial system. Therefore, the result of the Congo red test might be evaluated only in combination with other clinical and laboratory findings.

3. On the other hand, a certain prognostic value seems to adhere to the test. By grouping the patients according to their Congo red index and comparing the occurrence of death within the time of observation (six to nine months), we see the following distribution:

Group I:	C.R.I. 70-80	6 out of 20 patients died (30 per cent)
Group II:	C.R.I. 80-90	21 out of 39 patients died (54 per cent)
Group III:	C.R.I. 90-100	19 out of 27 patients died (70 per cent)

TABLE 11

*All dates refer to 1939 with exception of patients 1 to 4.

Therefore, the more severe disturbance of the reticulo-endothelial system appears to be connected with a more rapid fatal progress of the disease.

4. As shown in Table IV, the Congo red test was also repeatedly carried out in 12 cancer patients before, during, and after their treatment with radiation therapy. Here we see that in 2 patients (21, 37) the clinical improvement, achieved by the therapy, was also accompanied by a reversion of the Congo red index to normal values. In 2 patients (27, 66) the Congo red index was lowered, coinciding with a clinically observed radiation reaction and indicating an improved function of the reticulo-endothelial system, but no lasting clinical improvement was brought about. In the rest of the patients no clinical improvement was observed and the repeated performance of the Congo red test always

exhibited a damage of the reticulo-endothelial function. In patient 13 the regression of a breast lesion was also expressed by an improved reticulo-endothelial function, but the finally lethal recurrence was foreshadowed by an increase of the Congo red index, characteristic for the failure of the reticulo-endothelial function. As far as these few investigations permit us to judge, the repeated performance of the Congo red test during a treatment would prove valuable for prognostic purposes. In this connection it may be mentioned that these results support the opinion that successful radation therapy is accompanied by an activation of the reticulo-endothelial system or is partly dependent on it (Caspari,¹⁸ Lewin¹⁹).

*Numbers refer to corresponding cases in Table II.

5. In order to include a complete enumeration of our studies, we refer to the less conclusive results obtained by applying the Congo red test to 5 patients with sarcoma. Only in 2 of these was a decreased reticulo-endothelial function found: reticulum cell sarcoma, C.R.I. 85.8; fibromyxosarcoma, C.R.I. 100. In a case of fibrosarcoma of the intestines complete disappearance of the dye in the blood was observed after sixty minutes in a Congo red test performed twice (C.R.I. 0). No amyloidosis was found in the autopsy of this patient. In a patient with round-cell sarcoma a C.R.I. of 38.8, and in one with a reticulum-cell sarcoma a C.R.I. of 48.9 were found. While the number of the sarcoma patients studied is far too small to permit us drawing any conclusion, it does not seem

altogether improbable that the reticuloendothelial function is less frequently involved in sarcomas of mesodermal origin than in epithelial neoplasia. A similar view was expressed by Cramer²⁰ concerning the interpretation of reticuloendothelial studies made on rat sarcomas.

SUMMARY

A modification of the Congo red test has been described which can be used for clinical testing of the reticuloendothelial function. This test has been applied to 49 persons free of malignancy and to 100 patients afflicted with malignant neoplasms. A damaged function of the reticuloendothelial system was found in 86 per cent of the cancer cases. The possibility of a prognostic evaluation of this test was discussed as to duration of life and effectiveness of radiation therapy.

CLINICAL CHEMISTRY

VITAMIN K ACTIVITY OF 2-METHYL-1, 4-NAPHTHOQUINONE AND 4-AMINO-2-METHYL-1-NAPHTHOL IN HYPOPROTHROMBINEMIA*

E. A. SHARP, M.D., E. C. VONDER HEIDE, M.D., AND W. H. GOOD, M.D.
DETROIT, MICH.

IN VIEW of the promising preventive and curative role of vitamin K in hypoprothrombinemia, a brief communication is submitted on the recent chemical developments and the clinical status of synthetic vitamin K and substitute compounds.

MODE OF STUDY

Twenty-seven patients having hypoprothrombinemia below 40 per cent are reported. Specimens of blood were obtained by venipuncture during the morning hours. The prothrombin determinations were made by the method of Quick¹ and repeated at twenty-four-hour intervals when feasible. The normal clotting time for the method throughout the study was thirteen seconds, representing 100 per cent. Since many clinical variables must be considered in their eventual evaluation, this study involved only a preliminary assessment of activity of the chemical substances described when used in states of hypoprothrombinemia below 40 per cent of normal.

Dam² and Stokstad³ are identified with the early phases of research on a factor having antihemorrhagic properties. The former demonstrated its presence in vegetables and alfalfa. Almquist and Stokstad⁴ showed that a small percentage of alfalfa in the deficient diet prevented hemorrhagic tendency in chicks. Various contributions on the chemical nature of vitamin K cited by Doisy and his associates in a recent review⁵ preceded the investigations of McKee, Binkley, Thayer, MacCorquodale, and Doisy,⁶ and Binkley, MacCorquodale, Thayer, and Doisy⁷ which led to the isolation of vitamins K₁ and K₂.

Almquist and Klose⁸ reported on the antihemorrhagic property of a synthetic naphthoquinone, "phthiocol," 2-methyl-3-hydroxy-1, 4-naphthoquinone, which was isolated from the tubercle bacillus by Anderson and Newman⁹ in 1933. These former workers considered "phthiocol" to be the simplest member of a homologous series of antihemorrhagic substances. They found it possessed the same degree of potency whether given orally, intramuscularly, or intravenously, but it had only 1/100 to 1/20 the activity of vitamin K derived from alfalfa.

In May, 1939, Doisy and his co-workers^{11, 12} announced the isolation of two forms of vitamin K: K₁ from alfalfa and K₂ from fermented fish meal. As

*From the Anemia Laboratory, Out-Patient Department, Harper Hospital, and the Department of Surgery, Wayne University, College of Medicine, Detroit.
Received for publication, February 13, 1940.

result of chemical analysis it was suggested that K_1 and K_2 possessed quinonoid structures. Further study demonstrated vitamin K to be disubstituted 1, 4-naphthoquinone.

Doisy and his co-workers assigned to vitamin K derived from alfalfa the chemical formula of 2-methyl-3-phytyl-1, 4-naphthoquinone. This substance has been synthesized and when used in this pure form orally has been found to induce remission of hypoprothrombinemia in animals and man. It is oil soluble and stable in oily solution, assaying 1,000 curative chick units* per milligram. While not fully evaluated clinically, a dose range of 6,000 to 9,000 units daily is effective when the prothrombin deficiency is below 40 per cent of normal.

Further research on substances having quinonoid structures by Ansbaeher and Fernholz¹³ demonstrated that 2-methyl-1, 4-naphthoquinone, first discovered by Fries and Lohmann in 1921,¹⁴ possessed vitamin K activity. Each milligram of this substance assays about 2,000 curative chick units of vitamin K as determined by the seventy-two-hour method. It exists as bright yellow, prismatic crystals, possesses a quinone-like odor, and is affected by light; for example, exposure of the material in a glass-stoppered bottle to diffuse light for about two weeks not only changes the color to tan or off-white, but also raises the melting point from the normal range, 105° to 107° C., up to 170° C.

TABLE I

INEFFECTIVENESS OF 2-METHYL-1, 4-NAPHTHOQUINONE ORALLY IN DRY FORM IN HYPOPROTHROMBINEMIA OF OBSTRUCTIVE JAUNDICE AND BILIARY CIRRHOSIS

PATIENT NO.	PROTHROMBIN %		DAYS TREATED	DAILY DOSAGE (C.C.U.)*

7Pot	15	22	3	3,600
	25	30	14	2,400

*Curative chick units.

†Biliary cirrhosis.

The compound 2-methyl-1, 4-naphthoquinone is soluble in oil and manifests antihemorrhagic action when given orally. Sharp¹⁵ reported that doses of 1,200 to 7,200 curative chick units daily, when given orally in dry form, with or without whole bile, caused little alteration in hypoprothrombinemia associated with obstructive jaundice and biliary cirrhosis (Table I). When the same patients, however, received 2-methyl-1, 4-naphthoquinone dissolved in corn oil, a daily dosage of 2,400 to 4,800 units restored prothrombin to a satisfactory level within three to five days (Table II). Rhoads and Flicgelman¹⁶ have reported favorably on the use of 2-methyl-1, 4-naphthoquinone in prothrombin deficiency. In daily doses of 1 to 4 mg. orally only one of ten patients failed to respond and no toxic effects were encountered.

*The curative chick unit of vitamin K (J. Biol. Chem. 123: CXXI, 1938) may be described as the smallest quantity of a vitamin K preparation given over a three-day period which will produce an average coagulation time of ten minutes or less in at least 50 per cent of baby chicks which have been fed a vitamin K-free diet for the first fourteen to fifteen days. The unit corresponds to the activity of approximately 50 mg. of dry alfalfa.

*Confirmed.

†Tentative.

Given in doses of several milligrams daily for three to four weeks to numerous adult patients, 2-methyl-1, 4-naphthoquinone has developed no manifestations of intolerance. Rhoads and Fliegelman in their communication stated that they had given 0.5 mg. per kilogram of body weight without producing any

untoward phenomenon. It is the most potent of the oil-soluble vitamin K substances as judged by limited clinical experience.

Parenteral 4-Amino-2-Methyl-1-Naphthol Hydrochloride.—Further investigation of chemical substances having antihemorrhagic properties of vitamin K was continued in an effort to find a water-soluble and stable compound for parenteral use. This research resulted in the synthesis of 4-amino-2-methyl-1-naphthol and 4-amino-3-methyl-1-naphthol¹⁷ as the hydrochloride, both of which are water soluble and stable. It was found, however, that the former possessed definitely greater vitamin K activity by the curative chick method than the latter—actually almost three times greater than K₁.¹⁸ In Table III are given data on the use of 4-amino-2-methyl-1-naphthol hydrochloride in hypoprothrombinemia in man. Daily doses ranging from 1 mg. to 6 mg. (1,800 to 10,800 curative chick units in the form of the hydrochloride) given intravenously restored to normal severe prothrombin deficiency of obstructive jaundice within two to three days, while hemorrhagic states of the newborn responded within twelve hours to a dosage of 1 mg. intravenously (1,800 units).

DISCUSSION

Warner, Brinkhous, and Smith¹⁹ have reported extensive observations on the antihemorrhage effect of vitamin K in obstructive jaundice, as have Butt, Snell, and Osterberg.²⁰ Hellman and Shettles,²¹ and Waddell and Guerry²² have studied hypoprothrombinemia in expectant mothers and in the newborn. Hellman and Shettles, using vitamin K concentrate, demonstrated that the plasma prothrombin of the newborn can be raised by administration to the mother prior to delivery and by direct use in the infant. Waddell and Guerry also demonstrated therapeutic effectiveness of vitamin K concentrate and 2-methyl-1, 4-naphthoquinone on prothrombin deficiency in the newborn, and that prenatal administration may prevent intracranial hemorrhage associated with normal delivery.

Our unpublished observations on several hundred adult patients show that depleted prothrombin is not uncommon in blood disorders associated with or without jaundice. Hypoprothrombinemia in some of these conditions has responded to vitamin K, but a complete evaluation must be deferred.

The isolation and synthesis of vitamins K₁ and K₂ constitute an epochal chemical achievement. Projection of chemical research beyond this phase, however, promises therapeutic affluence within the partially defined limits of usefulness of antihemorrhagic factors.

The effectiveness of parenteral 4-amino-2-methyl-1-naphthol, the absence of signs of intolerance, and its rapidity of action imply that prevention of hypoprothrombinic bleeding in the newborn and adult will be a practical procedure. Further, that the control of bleeding associated with jaundice when surgical measures are urgent can be expected by the use of potent synthetic vitamin K substances by either the oral or the parenteral route of administration.

SUMMARY

A brief description of the chemical status of vitamin K₁ and synthetic substitutes having similar antihemorrhagic activity is given.

Seven patients having hypoprothrombinemia were ineffectively treated orally with 2-methyl-1, 4-naphthoquinone in dry form.

Five of the first series of seven patients and an additional six patients having prothrombin deficiency were successfully treated orally with 2-methyl-1, 4-naphthoquinone when the substance was dissolved in oil. No toxic effects were detected.

A water-soluble substance, 4-amino-2-methyl-1-naphthol hydrochloride, when given intravenously in hypoprothrombinemia, was effective in a majority of fourteen patients. Hemorrhagic tendency of the newborn responded rapidly. It has not produced toxic manifestations in the dosage used.

MEAT EXTRACTIVES IN STUDIES OF GASTRIC FUNCTION*

R. S. FISHER, B.S., AND FRANK L. APPERLY, M.D., RICHMOND, VA.

IT HAS long been recognized that meat extractives increase gastric secretion, but until recently there have appeared few data on the quantitative measurement of this response. Tessieri (1930)⁶ stated that ingestion of peptone preparations increased the duration and quantity of human gastric secretion. Komm (1931)⁴ reported that "Tago," a commercial meat hydrolysate, caused a marked increase in the gastric secretion of dogs. Smith and Cowgill (1933)⁵ reported the results of preliminary studies on gastric secretion following administration of various meat extracts. Wilhelmj, O'Brien, and Hill (1936)⁸ advocated a test meal of meat extractives and described its effect on gastric secretion in dogs.

The most important work of a quantitative nature which has been done on human beings appeared in 1939, when Upham and Spindler,⁷ using the test meal as evolved by Wilhelmj and associates, reported their studies of the response of the normal and of certain pathologic stomachs to the meat extractive secretagogue meal. This test meal was prepared by a rather lengthy and laborious treatment of a commercially available meat paste.

Meat extracts have been marketed for over sixty years and are prescribed in certain types of gastrointestinal dysfunction. Little is known, however, of the mechanism involved in the beneficial effects resulting from this therapy. This study was undertaken, therefore, with the dual purpose of obtaining quantitative data on the secretagogue power of a commercially available meat extract which would require little or no chemical treatment before administration as a test meal and of gaining information concerning the gastric response to the administration of a meat extract with the hope of explaining to some extent the mechanism of its action.

PROCEDURE

The test subjects used were healthy male medical students, acquainted with the use of the Rehffuss tube and the purposes of the investigation. The nature of the meals used, the lack of discomfort during the test period, and the reversal of the order of administration of test meal and control meal in one-half of the persons minimized and neutralized any possible psychic disturbances of gastric secretion. In fact, in individuals who were used repeatedly for the same test meal, the striking similarity of the secretory responses (noted by other observers) showed that our results were valid for comparative purposes.

The technique followed the usual procedure, viz., the introduction of the Rehffuss tube, aspiration of fasting contents after a rest of fifteen minutes, and

*From the Departments of Biochemistry and Pathology, Medical College of Virginia.
Received for publication, February 5, 1940.

the introduction of the previously warmed fluid meal via the tube. Samples were removed at fifteen minutes, thirty minutes, and at thirty-minute intervals thereafter. Care was taken to mix the stomach contents well before withdrawing each sample.

The meals used were: (a) The control meal, prepared by adding 25 Gm. of Ralston (a wheat cereal) to 750 c.c. of boiling water, boiling with stirring for ten minutes, allowing to stand for several hours and decanting 400 c.c. of supernatant fluid. To this was added 1 c.c. of phenol red (6 mg. per cubic centimeter, Hynson, Westcott, and Dunning). This preparation was cloudy owing to suspended starchy material. (b) The meat extract meal (used for series I) was prepared by the addition of 16 c.c. of meat extract,* neutralized to Töpfer's reagent with 5 N hydrochloric acid, to sufficient gruel (prepared as above) to make a total volume of 400 c.c.

Free acidity of the samples withdrawn from the stomach was determined by dilution and titration with fresh 0.01 N sodium hydroxide solution, using Töpfer's reagent as indicator; total chlorides were determined by the Van Slyke and Sendroy modification of Volhard's method; pepsin was determined by Mett's method. The amount of dilution of the gastric contents by various secretions was determined in the samples by comparison in a microcolorimeter of the color of the phenol red in the test meal (after alkalinization) with that of the standard meal used (also after alkalinization to bring out the color).

In series II and III where meat extract, diluted with water instead of gruel meal, was used, it was possible to determine the dilution with fair accuracy without any treatment other than the addition of alkali. Sometimes the brownish color of the standard was matched by adding minute amounts of meat juice to the unknown. Samples containing bile were matched by adding a trace of picramic acid to the standard. Where the suspended starchy material in the gruel meals interfered with color comparison, it was removed before alkalinization by suction filtration through asbestos mats. In most cases, however, an accuracy of 2.5 per cent could be obtained without such treatment, and it was felt that in laboratory practice the loss of time required to attain further accuracy would not be justified.

RESULTS

Fig. 1 shows the curves obtained by averaging the values for all samples at corresponding intervals in ten pairs of test meals. In plotting the total chloride curve for the meat extract meal, the analytical values obtained on the samples were first corrected for the chlorides contained in the test meal before ingestion (due to salt in the meat extract and to chlorides added as hydrochloric acid in neutralization to Töpfer's reagent). The following formula was used:

$$Cl_{int.} = A - A_0 X.$$

A represents the chloride concentration of the sample analyzed; X, the per cent of indicator present in the sample analyzed; and A_0 , the chloride concentration of the original test meal. (A_0 for the meal used in this investigation was 47 c.c. of 0.1 normal chloride per 100 c.c. of test meal.) Actually in in-

*The meat extract used in this investigation was kindly donated by the Valentine's Meat Juice Co., Richmond, Va.

dividual test meals somewhat higher peak values were often observed, but their distribution in the samples of different time intervals resulted in the average values shown.

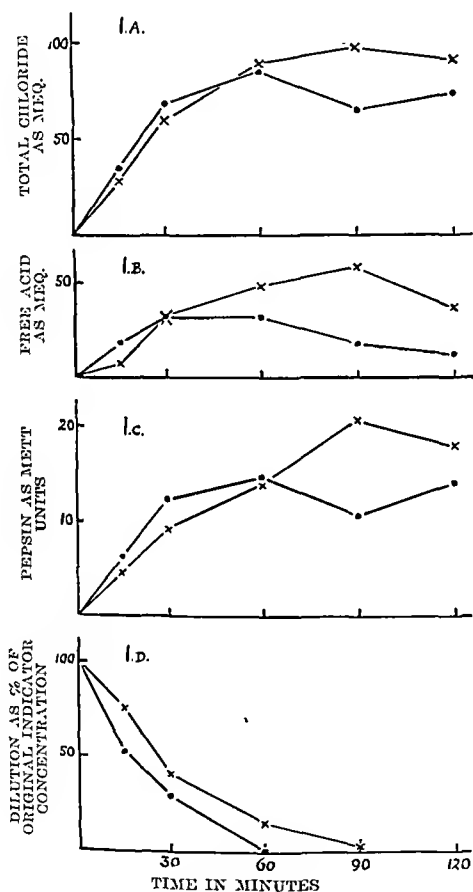

Fig. 1.—x x Gruel plus meat juice extract. • • Gruel meal.

As Fig. 1 shows, in the meat extract meal, and especially in the second hour, there is a higher concentration of total chloride, free acid, and pepsin. These differences occur only after the stomachs have emptied. This state of affairs might have been brought about by one of several things:

1. A greater secretion of acid gastric juice into the *meat extract* meal. This would also lead to a greater dilution of the meat extract meal than of the gruel meal, whereas actually the reverse has occurred (Fig. 1 D).

2. A greater secretion into the *gruel meal* of a chloride solution containing less hydrochloric acid than that secreted in the first hour. Since, however, in gastric juice of varying hydrochloric acid content the hydrochloric acid plus sodium chloride equals a constant of about 0.170 normal (Hollander),² the total chloride of the gastric secretion must remain unchanged. On the contrary Fig 1 A shows that in the case of the gruel meal the total chloride diminished rapidly in the second hour.

3. A regurgitation of duodenal fluids containing chloride and bicarbonate into the gruel meal. This possibility is the only one that can account for all the phenomena found, i.e., the lower total chloride, the relatively still lower free acid, the lower pepsin, and the greater dilution of stomach contents.

Fig. 2.—x x Gruel plus meat juice extract. • • Gruel meal.

In Fig. 2 these results, at least as regards the relationship of total chloride to free acid, have been compared in another way, by plotting the latter against the former. Hollander (1932)^{2,3} has shown that when various samples of pure gastric juice are drawn from animals, the plot of total chlorides against the corresponding free acid yields a straight line relationship. In our gruel and meat extract meal, where the gastric chloride and acid are diluted only by the fluid meal during the first hour, a similar straight line relationship exists; in the second hour other factors begin to operate, with fall of acidity. In the gruel meal, however, the free acidity very soon falls to the left of the straight line showing that alkalis (presumably of duodenal origin) are neutralizing the free acid only half an hour after the meal was placed in the stomach.

Apperly and Semmens (1928)¹ showed that high total chlorides, high acidity, and increased emptying time in healthy stomachs, indicate a high gastric muscle tonus. They further showed that the duodenum is not so readily able to regurgitate its contents into a hypertonic, relatively contracted stomach. This results in a higher acidity of the stomach contents, which in turn, as is well known, delays the emptying time, as judged by the disappearance of food starch, or dye from the stomach. These are the conditions found in the meat extract meal, which would, therefore, appear to be directly or indirectly responsible for the increased tonicity of the stomach. Clinically it is well known that the latter manifests itself in increased appetite and sense of well-being and thus probably accounts for the popularity of meat extracts during etc.

valescence and poor health. The increased concentration of acid and pepsin and the slower emptying time would also increase the rate and degree of digestion of certain foods.

A further series of test meals (series II) was prepared by dilution of 16 c.c. of meat extract to 399 c.c. with distilled water, and the addition of 1 c.c. of the phenol red solution as in the other test meals, but the results were not significantly different from those in series I. The peak acidity and pepsin values were reached sooner, but not as soon as with the gruel meal alone. Their values were approximately the same. Emptying time also was less than with the combination meal, but showed a delay when compared with the gruel meal.

A third (series III), using a 1:50 dilution of the meat juice, was done in order to study the effect of greater dilution of the meat extractives, the results being similar to those in series II, except that the peak values for concentration of secreted substances were reduced, indicating that the maximum effect of the meat extract was not being obtained. Since use of diluted meat extract alone produces results similar to those found with gruel plus meat extract, the use of meat extract alone as a test meal is advocated. Further work on this test meal is contemplated.

SUMMARY

An examination of the mode of action of a commercially obtainable meat extract was made in order to ascertain the physical basis, if any, for the commonly alleged sense of well-being accompanying the use of such extracts.

In comparison with the ordinary test meal alone, the addition of meat extract to the meal raises the concentration of total chlorides, free acid, and pepsin, and retards the dilution of the gastric contents. These facts are interpreted as indicating an increased tonicity of gastric muscle, which is known to be the physical basis of appetite.

Our experience with meat extract leads us to prefer this substance to all others for routine and experimental test meal work.

We wish to express our appreciation to Dr J. C. Forbes for his helpful suggestions during the course of this work.

FURTHER OBSERVATIONS ON THE ROLE OF DIET IN THE ETIOLOGY AND TREATMENT OF SPONTANEOUS HYPOGLYCEMIA*

L. W. SWANSON, M.D., AND JAMES A. GREENE, M.D., IOWA CITY, IOWA

THE manifestations of spontaneous hypoglycemia are sufficiently well recognized to require no further comment. There are apparently several causes for the syndrome, and once the diagnosis has been definitely established proper therapy cannot be instituted until the etiology is ascertained. It was assumed at first that all cases were due to an overproduction of insulin by the pancreas. This assumption led to the frequent feeding of carbohydrates to the milder cases and to surgical exploration for pancreatic tumor in the severe ones. It soon became apparent that pancreatic tumors were not present even in all of the extreme cases and that other etiologic factors must be considered. Faulty dietary habits appeared to be a likely etiologic factor in certain cases, and such a concept was supported by the fact that many patients became worse when treated with a high carbohydrate diet divided into several small meals daily. A low carbohydrate, high fat diet was proposed, therefore, as a therapeutic procedure by Clark and Greene,¹ and by Waters,² with successful results. Conn³ proposed a diet high in fat and protein, and low in carbohydrates after he observed a patient who had become worse with a high carbohydrate diet and did not improve with a high fat diet. He demonstrated that there was no appreciable hyperglycemia following such a diet and, therefore, there was no hypoglycemia. His patient was relieved of manifestations for a period of three months. Newburgh and Conn⁴ then observed six patients with spontaneous hypoglycemia and infectious hepatitis which was usually secondary to gall bladder disease. A cure was obtained in one case following removal of a diseased gall bladder. They attributed the disturbance of carbohydrate metabolism to the hepatitis.

Since the report of Clark and Greene,¹ we have observed eleven patients with spontaneous hypoglycemia due to faulty dietary habits. It was thought at first that all such cases were due to an excess carbohydrate intake until one patient who was observed in the Out-Clinic where the diagnosis was established, was admitted to the ward and given a high carbohydrate diet in an attempt to make the condition worse. On the contrary, the symptoms subsided and the glucose tolerance returned to normal. A careful dietary history then revealed that he had followed a high fat and low carbohydrate diet for several months prior to and after development of the spontaneous hypoglycemia. Since then we have

*From the Department of Internal Medicine State University of Iowa, College of Medicine, Iowa City.

Received for publication, January 30, 1940.

observed two other patients who have developed their symptoms while on a high fat and low carbohydrate diet. The remaining patients have followed a high carbohydrate and low fat type of diet. The two cases here presented are typical illustrations of the two types of faulty diets which will produce spontaneous hypoglycemia. Case 1 illustrates the high carbohydrate and low fat diet as an etiologic factor, and Case 2 illustrates the low carbohydrate and high fat dietary type.

CASE 1.—A male dry cleaner, aged 32 years, entered the University Hospitals in July, 1937, because of a stone in the right lower ureter. His symptoms disappeared after spontaneous passage of the stone, but he returned in March, 1938, complaining of vague abdominal pain, constipation, palpitation, and nervousness. No organic disease was discovered and he was sent home without treatment.

Fig. 1.—The eradication of hypoglycemia in Case 1 by a diet high in fat and low in carbohydrate, as shown by the double glucose tolerance curves.

He returned again in September, 1938, however, complaining of increasing nervousness and irritability, weakness, hunger, palpitation, fatigability, insomnia, mild constipation, slight abdominal distress, and loss of five pounds of body weight in spite of an excellent appetite. Most of these symptoms occurred two or three hours after each meal, and were severe enough to force him to stop work. Food relieved the symptoms at such times sufficiently for him to resume work, and hence he habitually ate between meals. A bedtime snack would also prevent the symptoms at night. His diet had been extremely high in carbohydrate and low in fat, primarily because of a dislike for fatty foods.

The physical examination revealed no noteworthy abnormalities. The double glucose tolerance curve (curve I, Fig. 1) was typical for hypoglycemia. After six days of a diet containing 70 Gm. of protein, 116 Gm. of carbohydrate, and 211 Gm. of fat, the double glucose tolerance curve (curve II, Fig. 1) was within normal limits and the symptoms had disappeared completely. He was discharged with a diet containing 80 Gm. of protein, 170 Gm. of carbohydrate, and 200 Gm. of fat.

He returned four months later entirely free of symptoms, and the glucose tolerance curve (curve III, Fig. 1) continued within normal limits. He was sent home with instructions to follow a diet containing 125 Gm. of protein, 200 Gm. of carbohydrate, and 250

Gm. of fat, and to return to the clinic if the symptoms reappeared. A report one year later stated that he was entirely free of symptoms.

CASE 2.—A farmer, aged 28 years, entered the University Hospitals in 1935, because of abdominal distress, nervousness, palpitation, and sweating. He had enjoyed good health until 1936, when alternating constipation and diarrhea, heartburn, water brash, vomiting, and slight generalized abdominal distress appeared. He was examined by his local physician who prescribed a bland diet. In addition, because of a dislike for carbohydrate foods, the patient reduced the carbohydrate content of his diet to a minimum. The symptoms disappeared, but several months later they returned and were accompanied by weakness, palpitation, and sweating. These symptoms occurred two to three hours after meals, and it was soon discovered that eating between meals would give relief until the next meal. The symptoms increased, however, and became so severe that he had to stop work.

Fig. 2.—Hypoglycemia disappeared in Case 2 following a diet high in carbohydrate and low in fat, as shown by the double glucose tolerance curves.

The physical examination revealed no noteworthy abnormalities. The gastroenteric tract was normal to roentgen-ray studies. The glucose tolerance curve (curve I, Fig. 2) was typical of hypoglycemia. The patient was sent home for three weeks with instructions to follow a diet containing 500 Gm. of carbohydrate daily. He did not follow the instructions completely, but the symptoms were less when he returned and the double glucose tolerance curve (curve II, Fig. 2) was improved. He was discharged with the advice to follow the instructions and to return in three months. He returned two and one-half months later, stating that he had followed the diet, that his symptoms had completely disappeared, and that he had resumed work. The double glucose tolerance curve (curve III, Fig. 2) was greatly improved. He was instructed regarding a diet containing 90 Gm. of protein, 350 Gm. of carbohydrate, and 175 Gm. of fat before discharge and advised to return if his symptoms reappeared. A report one year later stated that he was entirely well.

COMMENT

There appear to be several causes for spontaneous hypoglycemia. Once the diagnosis is established the etiology must be ascertained before proper treatment can be instituted. The known causes for spontaneous hypoglycemia are (1) an oversecretion of insulin due to either tumor of the pancreas or hyperplasia of the

islets of Langerhans; (2) Addison's disease; (3) probably certain pituitary dysfunctions; (4) infectious hepatitis, which is usually secondary to gall bladder disease; and (5) faulty dietary habits. The syndrome can be produced by either extreme in the carbohydrate and fat content of the diet: A high carbohydrate and low fat diet or a low carbohydrate and high fat diet can produce the manifestations.

It is usually not difficult to establish the etiology in a given case. The manifestations in patients with an oversecretion of insulin are usually extreme and are not improved by dietary therapy, although they may be partially or entirely alleviated as long as adequate and frequent carbohydrate intake is continued. Addison's disease is not likely to be overlooked if its presence is once considered. The presence of pituitary dysfunction can be ascertained only when there are other manifestations of such dysfunction, and these cases are undoubtedly extremely rare. An infectious hepatitis may produce severe manifestations, and these cases are probably more common than the above-mentioned ones. A thorough study of the biliary tract is indicated in each case of spontaneous hypoglycemia, but the absence of evidence of gall bladder disease does not absolutely exclude hepatitis, nor does the presence of gall bladder disease definitely establish its presence. In patients with spontaneous hypoglycemia due to faulty dietary habits the manifestations are usually mild, but occasionally they are severe. There are many functional complaints in patients with spontaneous hypoglycemia due to faulty diets, and these complaints frequently obscure those of hypoglycemia. In fact, the functional complaints have caused most of these patients to follow the abnormal diet. The eradication of the hypoglycemic manifestations does not cure such patients, but the neurotic tendencies cannot be controlled as long as the symptoms of hypoglycemia persist. A careful dietary history is necessary, therefore, in such cases to ascertain whether or not the previous diet has been high in fat or high in carbohydrate. A high carbohydrate diet will not eradicate hypoglycemia if this type of diet has produced it, but a high fat diet will correct it. The reverse is true if a high fat diet produced the syndrome.

If the manifestations are extreme, the etiology of a given case of spontaneous hypoglycemia is most likely an infectious hepatitis or an overproduction of insulin from a pancreatic tumor. The former etiologic factor can be ascertained fairly accurately by a careful study of the biliary tract. On the other hand, the etiology is most likely an infectious hepatitis or a faulty diet if the manifestations are mild or moderately severe. The latter, in our opinion, is the most common cause for spontaneous hypoglycemia and can be uncovered by a careful dietary history and by the response to a diet which contains carbohydrate and fat in the reverse proportion to that which the patient has followed previously.

The time required for such diets to eradicate hypoglycemia in these patients varies considerably. It has required from six days to six months in our patients. The minimum duration for such dietary regimen after correction of the hypoglycemia is not known. We have assumed that the patients who respond quickly need not follow such a diet as long after correction of the hypoglycemia as those who are slower to respond. We, therefore, have advised our patients to

adhere to such diets for periods varying from three weeks to two and one-half years after the hypoglycemic manifestations have subsided. Probably such patients should be re-examined at three- to six-month intervals during therapy.

It is important that the patient be informed of the cause of the manifestations and that adequate general dietary instructions be given which will prevent a repetition of dietary mistakes after the specific dietary regime has been discontinued.

SUMMARY

The causes of spontaneous hypoglycemia have been discussed and those due to faulty diets have been emphasized. The syndrome can be produced by diets low in carbohydrate and high in fat, or by those high in carbohydrate and low in fat. Three cases due to the former and eight due to the latter have been observed, but only one case illustrative of each dietary etiology is reported. The types of corrective diets and the duration of therapy have been discussed.

THE EFFECT OF COPPER AND IRON ON HEMOGLOBIN REGENERATION*

WILLIS M. FOWLER, M.D., AND ADELAIDE P. BARER, Ph.D.
IOWA CITY, IOWA

THAT copper plays a role in the synthesis of hemoglobin has been conclusively demonstrated, but since it is not a part of the hemoglobin molecule, the exact mechanism of its action has not been ascertained, and the clinical implications to be drawn from animal experimentation are not entirely clear. The numerous reports concerning its effect on the anemia of experimental animals have been adequately summarized.¹⁻⁵ The present concept, in brief, is that copper acts as a catalytic agent in hemoglobin formation and aids in the mobilization and utilization of iron stored in the body as well as augmenting the effect of inorganic iron salts administered by mouth. These effects are illustrated by the fact that neither iron nor copper alone are effective in the treatment of nutritional anemia in the rat, whereas a combination of the two produces a rapid hemoglobin response. When iron has been given to an anemic rat without producing a hemoglobin response and its administration then discontinued, it has been found that copper alone will then produce rapid hemoglobin regen-

Received for publication, February 21, 1940.

eration by aiding in the utilization of the iron previously stored.³ The results in chronic anemia in dogs have been similar but less consistent than those observed in rats.^{6, 7}

The clinical reports on the use of copper and iron in the treatment of anemia are conflicting. An increase in the hemoglobin of infants has been reported following the use of 25 mg. of iron and 1 mg. of copper daily, and in severe nutritional anemia the hemoglobin response has been rapid. When the same amount of iron was administered alone, the response was less satisfactory.^{8, 9} This combination of copper and iron not only has been more effective than iron alone in raising the hemoglobin level but also has caused a greater gain in weight and lessened the incidence of infections among infants.¹⁰ In adults the administration of copper and iron has been reported to be effective in "secondary anemia,"¹¹ idiopathic hypochromic anemia,¹² and in anemia which accompanies the therapeutic use of malaria.¹³ Other reports have indicated that the addition of copper to an inorganic iron salt was not necessary,¹⁴ and in a study of a group of college women iron alone produced as good results as did the combination of iron and copper.¹⁵ It has been assumed in the cases in which iron alone has produced a satisfactory response that either there was no copper deficiency or there was sufficient copper obtained from the food or as a contaminant of the inorganic iron salt.

In a previous report¹⁶ concerning the effect of copper on iron metabolism in adult patients with hypochromic anemia, it was shown that the addition of copper sulfate to a relatively small dose of iron and ammonium citrates (217 to 261 mg. of elemental iron per day) led to a diminution in the amount of iron retained by the body but that hemoglobin regeneration was active in spite of the diminished iron retention. In two other patients receiving larger amounts of iron and ammonium citrates (426 and 517 mg. of iron per day) the addition of copper sulfate did not influence the retention of iron. In both groups of patients hemoglobin regeneration was active regardless of the amount of iron retained, but in neither group was the increase more rapid than that obtained with iron alone.

In an attempt to gain further information on the effect of copper on hemoglobin formation, 20 patients with mild grades of hypochromic anemia were selected for study. All were females and all were nurses, students, or hospital employees who would cooperate and who could be depended upon to take the medication regularly. One patient was found to have menorrhagia and was dropped from the study, and others dropped out after the first and second periods. The study was divided into three periods, each of six weeks' duration. During the first period the patients received 0.5 Gm (7.5 grains) of iron and ammonium citrates daily. During the second period they received the same amount of iron plus copper sulfate, and during the third period the copper was discontinued but the dose of iron and ammonium citrates was increased to 1 Gm. daily. Hemoglobin determinations by the Newcomer method, erythrocyte counts, and hematocrit determinations were made at approximately two-week intervals on all patients. Except for the initial readings, only the hemoglobin values are recorded in this communication, since these present the essential information. All medications were supplied in gelatin capsules.

RESULTS

Period I. Iron and ammonium citrates 0.5 Gm. per day (approximately 85 mg. of elemental iron). At the onset of therapy the blood hemoglobin values ranged from 8.46 to 11.57 Gm. per 100 c.c., with an average of 9.88 Gm. for the 19 patients. Following the administration of iron for forty-two days, the average gain in hemoglobin per patient was 0.41 Gm. The gain or loss for each patient is shown in Table I. The greatest increase in hemoglobin was

Average gain					+0.415		+0.233		+0.336

found in Case 11, who had an initial hemoglobin value of 10.37 Gm. and during the six-week period showed a gain of 1.2 Gm. In 3 patients (Cases 2, 13, and 16) there was no hemoglobin increase, and in 2 patients (Cases 7 and 17) there was a decrease in spite of this therapy. This slow and inconsistent hemoglobin increase cannot be considered as a satisfactory response to an anti-anemic remedy, but this small dose of medicinal iron was purposely chosen so that the response would not be adequate. It was felt that if copper was of value in increasing the effectiveness of inorganic iron in hemoglobin formation, it would be manifest by an increased rate of regeneration when the copper was added to a small dose of iron. By using an amount of iron too small to be efficient, the beneficial effects of copper would not be masked by the rapid increase obtained with large doses of iron.

Period II. Iron and ammonium citrates 0.5 Gm. per day plus 3 mg. of copper as copper sulfate (ratio of Fe to Cu 28:1). Four patients discontinued treatment after the first period, leaving 15 under observation during the second period. The hemoglobin values ranged from 9.47 to 11.78 Gm., with an average of 10.43 for the 15 patients. During this period of six weeks the average gain in hemoglobin was 0.23 Gm. The greatest increase was in Case 15, with a gain of 0.87 Gm. In one patient (Case 5) there was no increase in hemoglobin, and

in 4 patients (Cases 6, 11, 13, and 18) there was a decrease. In 6 patients the hemoglobin increase was more rapid with copper and iron than it had been with iron alone; in one patient it was the same; but in the other 8 patients it gained more rapidly before the addition of copper. The average hemoglobin increase was lower than that obtained with the same amount of iron alone, so that the addition of copper did not appreciably increase the effectiveness of inorganic iron. The average hemoglobin level at the onset of treatment with copper and iron was slightly higher than when iron alone was started (10.43 Gm. as compared to 9.88 Gm.), but this is not great enough to make an appreciable difference.

Period III. Iron and ammonium citrates, 1 Gm. daily (approximately 170 mg. of elemental iron) without copper sulfate. Nine patients were followed through the third period and received twice the amount of iron previously administered. The blood hemoglobin values at the start of the period ranged from 9.77 to 11.36 mg., with an average of 10.50 Gm. The average gain in hemoglobin per patient for this six-week period was 0.34 Gm. The greatest gain was 1.71 Gm. in Case 19. Three patients failed to gain (Cases 12, 14, and 18), and one (Case 11) showed a decrease. The average hemoglobin increase was greater than that obtained with half the amount of iron plus copper sulfate and shows that the patients still have the ability to respond when iron is available in sufficient amounts.

It has been our experience with iron therapy that (in patients with mild anemias) a peak in hemoglobin regeneration is reached and thereafter there is a slight drop in the hemoglobin level even though the iron is continued. In this group of 9 patients such a peak was reached before the end of the period (in 6 instances), and a subsequent drop in hemoglobin occurred. Had the hemoglobin gain been calculated from the highest level rather than the reading at the end of six weeks, the average gain would have been 0.54 Gm. rather than 0.34 Gm.

It is possible that the greater hemoglobin increase during period III as compared to period II might be due to the copper which was stored in the body during the preceding six weeks rather than to the increased amount of iron administered. However, in another group of 12 patients with a similar hemoglobin level (10.32 Gm. per 100 c.c.) who were started immediately on 1 Gm. of iron and ammonium citrates per day, there was an average gain of 1.29 Gm. of hemoglobin during a six weeks' period. This is still greater than the gain recorded in the 9 patients during period III and indicates that the increased effect was due to the increased amount of iron rather than to the previously administered copper.

SUMMARY

The addition of copper sulfate to an inorganic iron salt did not increase the effectiveness of iron in hemoglobin regeneration in mild hypochromic anemias in the adult.

IODINE ABSORPTION BY THE SERUM OF EPILEPTIC PATIENTS ON BROMIDE THERAPY*

IRVING C. SHERMAN, M.D., AND ALEX J. ARIEFF, M.D., CHICAGO, ILL.

BECAUSE of the differences of opinion in the literature we were prompted to investigate the iodine absorption values of the serum in a group of epileptic patients on sodium bromide therapy. An effort was made to determine whether the bromide caused any saturation of the unsaturated fatty acids of the serum, and hence be a possible explanation of the common occurrence of skin eruptions on bromide medication. The iodine absorption value was correlated with the level of serum bromide. Cholesterol studies were also done on this group of patients.

During their studies on the nature of serum antitrypsin, Jobling and Petersen⁷ showed that the ferment-inhibiting properties of the serum are due to the presence of compounds of the unsaturated fatty acids. They also showed that the iodine absorption value of a serum treated with potassium iodide falls to almost one-fifth of its original value—an effect which is probably due to the liberation of small amounts of free iodine from the potassium iodide which can then saturate the unsaturated carbon bonds. Furthermore, they concluded that the influence of iodine in removing the inhibiting action of serum shows that the inhibiting agents belong to the unsaturated group of fatty acids. From

this was evolved the following explanation for the cause of acne in patients on bromide and iodide therapy. It was suggested that the bromine and iodine radical neutralize the unsaturated fatty acid antitryptic effect. This allows the proteolytic ferment to produce proteotoxins and thus produce the skin eruptions.

Subsequent to this Burr and Burr¹ observed that young rats restricted to fat-free diets do not thrive and develop scaldiness of the skin and tail, which could be prevented or alleviated by adding unsaturated fatty acids to the diet. They used linoleic or linolenic acid and termed them "essential fatty acids" because of this ability. In 1933 Hansen⁵ investigated the significance of the unsaturated fatty acids in cases of infantile eczema. He showed that in 21 determinations on 10 infants with eczema the amount of iodine absorbed per 100 c.c. of serum ranged between 280 and 487, with an average of 383 mg. per 100 c.c. of serum. In 18 determinations on 16 control infants the amount of iodine absorbed per 100 c.c. of serum ranged between 460 and 711, with an average of 539 mg. per 100 c.c. of serum. The average iodine number of the serum fatty acids in the eczema group was 84, and in the control group was 111. He concluded that the serum fatty acids are more saturated in cases of infantile eczema than in control infants. He⁶ also reported that in infants with intractable eczema clinical improvement was shown when oils rich in unsaturated fatty acids were administered internally for various lengths of time. This was associated with a rise to normal of the iodine numbers of the serum lipids. This could not be confirmed by Faber and Roberts,³ who could find no difference between the incidence of recovery for patients treated this way and those subjected to the usual therapeutic procedures. Taub and Zakon,⁸ working on a small series of cases of atopic dermatitis (neurodermatitis), concluded that some patients were actually worse off after taking raw linseed oil internally.

Cornbleet² is the only one who confirms Hansen's opinion. He reported uniformly good results when oils rich in unsaturated fatty acids were given to a large series of patients with chronic eczema. This was again denied in 1937 by Ginsberg, Bernstein, and Iob,⁴ who could find no characteristic abnormality of the blood lipids in patients treated, or that any specific benefit arises from feeding such patients oils containing highly unsaturated fatty acids.

METHOD

Blood was drawn in the morning on a fasting stomach. The blood was allowed to clot and the serum was removed. One cubic centimeter of serum was extracted with three parts alcohol and one part ether. When cooled, it was made up to a volume of 50 c.c. Ten cubic centimeters of this extract were used for the cholesterol determination according to Bloor's oxidative method. The remainder of the extract was used for the determination of amount of iodine absorbed per 100 c.c. of serum. The blood bromide values were determined in almost all cases on a blood specimen drawn on the same day by the Wuth colorimetric method.

The iodine absorption value of the serum was determined by the micro-method of Rosenmund and Kulnhenn, as modified by Page, Pasternack, and Burr.⁹ Yasuda's¹⁰ technique was used except that 0.01 N thiosulfate was used for titration.

In this work we took the number of milligrams of iodine absorbed per 100 c.c. of serum (after correcting for the cholesterol factor) as being quite indica-

tive of the iodine number of the total unsaturated fatty acids. We believed this tenable because practically the only substances in the serum that will absorb iodine are unsaturated fatty acids and cholesterol. In addition, the alcohol-ether mixture extracts only lipoids. Since the amount of iodine absorbed by the cholesterol was deducted in the formula, it is correct to say that N equals the number of grams of iodine absorbed by the unsaturated fatty acids in 100 c.c. of serum. It has been shown in the work of Hansen and Boyd^{6, 11} that the fatty acids are fairly constant in amount in different individuals. In Hansen's infants there was practically no difference in the fatty acid content of the serum regardless of whether they had eczema. Hansen's work clearly indicates that N parallels the iodine number of the fatty acids. We feel justified, therefore, in considering N as being indicative of the degree of unsaturation of the fatty acids in the serum. This made it possible to avoid the long and complicated procedure of actually measuring the quantity of fatty acids.

The figures for N represent the number of milligrams of iodine absorbed by the fatty acids in 100 c.c. of serum, i.e., exclusive of the cholesterol. These are not exactly comparable to those quoted from Hansen because he gave values for the amount of iodine absorbed by both cholesterol and fatty acids.

RESULTS

I. Cholesterol Values.—Cholesterol values were determined in 45 instances on 41 epileptic persons, divided into two groups: (1) those who had not started taking sodium bromide, or whose blood bromide was too low to be estimated; (2) those who had a measurable amount of bromide in the blood.

Group I—11 determinations.

The range of cholesterol was from 171 to 294 mg. per 100 c.c. of serum. The average value was 209. These limits are reasonably close to the normal cholesterol range of 160 to 250 mg. per 100 c.c. of serum.

Group II—34 determinations.

The range of cholesterol was from 132 to 368 mg. per 100 c.c. of serum. The average value was 203. There were only 8 determinations over 250, and 2 of them were on a patient with hypothyroidism. There was no significant alteration in the serum cholesterol values of epileptic persons on sodium bromide therapy.

II. Relationship of Cholesterol Values to Blood Bromide Level.—The patients were grouped into four classes according to the blood bromide level. The cholesterol values in each group were averaged with the following result:

Blood Bromide Range	Average Cholesterol in this Range
75 to 150	240 (6 cases)
151 to 200	230 (15 cases)
201 to 250	240 (8 cases)
251 to 300+	204 (5 cases)

These data indicate that the level of bromide in the blood had no material effect upon the cholesterol value. The group from 251 to 300+ mg. of sodium bromide per 100 c.c. serum had a lower average cholesterol than the others but was well within normal limits and is, therefore, not significant.

III. Relationship of Acne to Blood Bromide and Cholesterol Levels.—A survey of Table I shows distinctly that the severity of the acne is independent

of the blood bromide level. In those patients who have mild acne or seborrheic skin prior to bromide medication it was noticed that the bromide usually caused an exacerbation of the skin lesions. This was independent of the quantity of bromide ingested or of the level to which the blood bromide had been elevated. It was also noted that the age of this susceptible group was roughly in the adolescent and postadolescent period.

TABLE I

Mean iodine value is 508; median iodine value is 527.

CASE NO.	AGE	IODINE ABSORPTION VALUE	SERUM BROMIDE	SERUM CHOLESTEROL	ACNE	REMISSION RATING
1	39	698	-75	203	++	R.X.
2	42	692	150	227	+	F.R.

18	33	533	275	208	+	I.R.
19	39	527	200	250	+++	Same case as No. 1.
20	27	526	160	250	+	Re.
21	15	508	190	297	+	R.X.
22	9	507	165	186	0	I.R.
23	35	503	275	193	+++	F.R.
24	60	495	190	272	0	F.R.
25	19	489	260	227	0	F.R.
26	7	467	250	368	0	I.R.
27	28	464	110	234	0	F.R.
28	17	464	220	188	+	F.R.
29	20	457	160	227	0	R.X.
30	40	438	135	321	+	I.R.
31	50	397	110	208	0	F.R.
32	16	394	0	171	++	--
33	22	371	160	132	++	R.X.
34	52	362	160	216	0	F.R.
35	9	330	300	208	0	F.R.
36	17	314	170	182	++	R.X.
37	17	277	235	150	++	Same as No. 36.
38	21	108	300+	184	+++	R.X.

It is also apparent that there is no relationship between the amount of cholesterol in the blood and the severity of the acne. The patients were classified into four groups, according to the severity of the acne. The average cholesterol value for each group is indicated below:

Acne
0 (No acne)
+ (Mild)
++ (Moderate)
+++ (Severe)

Average Cholesterol

234 (13 cases)
242 (16 cases)
200 (8 cases)
203 (5 cases)

From these data there appears to be some difference between the two extremes of no acne and +++ acne. This difference is of no significance clinically, since both extremes are in the normal range.

IV. Relationship of Iodine Absorption to the Blood Bromide Level.—In 34 patients the iodine absorption value of the fatty acids of the serum was measured on the same specimen of blood as was the blood bromide. These patients had been on sodium bromide for varying periods of time and their blood bromide levels varied from -75 to 300+ mg. of sodium bromide per 100 c.c. of serum. One can see that there is very little relationship between the amount of iodine absorbed by the fatty acids in 100 c.c. of serum and the blood bromide level. A perusal of Table I reveals a range of iodine values from 698 down to 108. The blood bromide values ranged from -75 to 300+. In only very occasional instances was a high iodine value correlated with a low blood bromide value. There were many more instances in which such a correlation did not exist.

V. Relationship of Iodine Absorption Value to the Presence of Acne.—A general survey of Table I shows that there are cases of acne distributed over the whole range of iodine absorption values from 108 to 698. This would, therefore, appear to yield a negative result. That is to say, it is not probable that the bromide taken orally serves to saturate any unsaturated fatty acids and thus inactivate the antitryptic ferments. However, if one derives an average iodine absorption value (508), it is apparent that there are 18 cases of acne above this average and only 8 cases below. This would seem to indicate that there is a general tendency for acne to occur more readily in patients with a high iodine absorption value than in those with a low value. In other words, it appears that the higher the level of unsaturated fatty acids the easier it is for acne to occur. This is exactly opposed to the original theory of Jobling and Petersen.

Table I shows that there are 20 patients in the scale above the average iodine absorption value and 17 below the average. Of the 20 above the average there are 13 under 30 years of age and 8 under 20 years of age, the average age being 27 years. Of the 17 below the average there are 12 under 30 years of age and 9 under 20 years of age, the average age being 26 years. Therefore, it can be stated that the general tendency for greater prevalence of acne in the group with higher iodine absorption values is not determined by the difference in ages of the two groups.

VI. Relationship of Iodine Absorption Values to Remissions of Convulsions.—In this group of patients 31 were followed and classified according to response to treatment.

1. Initial Remission. There were four patients who had a remission over six months of all spells at the onset of treatment. The iodine absorption value ranged from 438 to 533, with an average of 486.

2. Final Remission. Fourteen patients eventually had a remission of all spells lasting six months or more. The range of iodine absorption value was 330 to 692, with an average of 504.

3. Remissions and Exacerbations. Eleven patients showed improvement by remissions of all spells for periods of two to three months alternating with exacerbations of spells. The range of iodine absorption values was from 108 to 660, with an average value of 484.

4. Recalcitrant. In this group of two patients no improvement occurred. The iodine absorption values were 661 and 526, with an average of 593. The group was too small to be of significance.

The values in the first three groups are too close to be of any significance. There is no correlation between iodine absorption value and response to therapy with sodium bromide.

SUMMARY AND CONCLUSIONS

1. The cholesterol values in 41 patients with epilepsy revealed no significant deviation from normal prior to or during therapy with sodium bromide.
2. There was no correlation between the blood bromide level and serum cholesterol in patients on bromide therapy.
3. Acne may occur in patients on bromide therapy regardless of the blood bromide level or serum cholesterol level. Those patients with acneic or seborrheic skin were more prone to an exacerbation of their skin lesions.
4. The iodine absorption value found in our study ranged from 108 to 698, with an average of 508. There was no significant relationship between the blood bromide level and the amount of iodine absorbed by the blood serum.
5. There was no definite correlation between the iodine absorption value and the presence or severity of acne. We did not find that the acne of epileptic patients on bromide therapy was associated with a low level of unsaturation of fatty acids.
6. The response to treatment with sodium bromide was not dependent on the iodine absorption value of the blood.

THE STUDY OF ACETYLCHOLINE IN URINE

MIHAJLO MATANOVITCH, M.D., Sc.D., PHOENIX, ARIZ.

ACETYLCHOLINE is an organic nitrogenous substance found physiologically in very small amounts in every body cell. It acts as a chemical transmitter of nervous impulses from the motor nerve endings to the muscle end plates.

Elliot was the first to suggest that automatic nerves transmit their impulse at their nerve endings by releasing some specific chemical substance, and Loewi later showed that parasympathetic effects are transmitted by release of acetylcholine. It was found that two chief specific substances were liberated by the nerve fibers: acetylcholine (unstable ester of choline) and an adrenalin-like compound.

Sir Henry Dale called the nerve fibers that liberate the adrenaline-like compound at their terminals "adrenergic" and those that liberate the acetylcholine "cholinergic." Cholinergic fibers are (1) preganglionic fibers of the whole sympathetic system, (2) postganglionic fibers of the parasympathetic system, and (3) motor fibers of the voluntary muscle.

When a preganglionic impulse arrives at the synapse, very small amounts of acetylcholine are liberated to play an important part in transmitting the impulse to the autonomic ganglionic cell and to influence the action of the muscle and gland cells. Feldberg and Dale demonstrated that some postganglionic fibers of the true sympathetic system transmit their effects by means of acetylcholine. Dale thinks that the action of acetylcholine must be on the effector cells and not on the nerve endings. It seems that the transmitting substance is held inactive and is released when the nerve impulse arrives.

Ergehart (1931) showed that this depot of the transmitting substance depends for its maintenance on the integrity of the nerve endings and that it disappears or becomes depleted when the nerve fibers start to degenerate.

Mott and Halliburton were unable to find the choline or its unstable ester in urine with their chemical method. Guggenheim and Loeffler described a biological method by which they were able to extract acetylcholine from urine in the smallest negligible amounts. After numerous experiments they found that a 1:1,000,000,000 solution of synthetic acetylcholine will produce minimal peristaltic movements on the small intestine of a guinea pig, and that the amount of urine necessary to produce same minimal peristalsis should contain 0.000.001 mg. acetylcholine.

Method.—From a twenty-four-hour urine specimen 2 c.c. of urine were collected, evaporated, treated with alcohol and acetylchloride, neutralized, and

finally diluted up to an amount of 100 c.e. This solution was then examined in very small increasing amounts on the small intestine of a guinea pig, and the slightest peristaltic movement was carefully recorded.

Fig. 1.—Bronchopneumonia.

Fig. 2.—Locomotor ataxia.

Fig. 3.—Myasthenia gravis.

Fig. 4—Myasthenia gravis (after treatment with prostigmine).

Two cubic centimeters of urine were collected from a twenty-four-hour specimen (800 c.e.) and treated by the above-mentioned method. Choline was transformed into acetylcholine, neutralized, diluted to 100 c.e., and the resulting solution examined on the intestine of the guinea pig (Fig. 1). Two-tenths cubic centimeter of the solution did not record any peristaltic movement; 0.3 c.e. of the solution recorded minimal peristalsis; 0.5 c.e. of the solution recorded strong peristalsis; and 0.1 c.e. of acetylcholine solution that contains 0.000.001 mg. of acetylcholine recorded the same peristaltic movements as 0.3 c.e. of the examining solution, which contains the same amount of 0.000.001 mg. of acetylcholine. The whole amount (100 c.e.) of the examining solution contains $\frac{0.0001}{0.3}$

or 0.00033 mg. of acetylcholine. As 100 c.c. of the examining solution was prepared from 2 c.c. of a twenty-four-hour urine specimen (800 c.c.), the amount of acetylcholine in the whole daily specimen will be: $0.0003 \times \frac{800}{2} = 0.132$ mg

Making a study with the foregoing method, I extracted choline in the form of acetylcholine from the urine of 120 patients. In patients suffering from nephritis, arteriosclerosis, and vitium cordis, acetylcholine was found in very small amounts in urine. In five patients with myasthenia gravis treated with prostigmine, acetylcholine was eliminated in urine in very negligible amounts (0.016 to 0.100 mg.).

It was very interesting to find that choline and acetylcholine were eliminated in larger amounts in the urine of patients suffering from parasymphilitic diseases of the brain and spinal cord. In six persons with locomotor ataxia and one with general paresis with positive Wassermann test, acetylcholine was found in urine in very large amounts. In three patients with myasthenia gravis acetylcholine was eliminated in urine in surprisingly large amounts of 0.350 mg., 0.450 mg., and 0.500 mg. (in a twenty-four-hour urine specimen).

CONCLUSION

From my experiments it is evident that choline and its unstable ester "acetylcholine" stored in the nerve fibers become depleted and are eliminated in the urine in unusually large amounts in patients suffering from parasymphilitic diseases of the brain and spinal cord.

It seems that in myasthenia gravis accelerated destructive action of choline esterase is inhibited by the administration of prostigmine and the elimination of the substance in the urine is greatly decreased.

CHOLINESTERASE DETERMINATIONS*

ROLAND C. HAWES, B.S., AND GORDON A. ALLES, PH.D., LOS ANGELES, CALIF.

NUMEROUS methods have been proposed and used for the estimation of the cholinesterase content of blood or tissues. Their variety has resulted from most investigators in the field making an arbitrary choice with regard to one or more of the several variables that affect cholinesterase activity. The methods fall into two classes, depending upon whether bio-assay is used to measure residual acetylcholine after enzyme action has occurred, or whether the acetic acid produced is estimated by a suitable chemical method.

The two classes of methods differ in some important respects. The bio-assay methods are usually carried out at low substrate concentrations, the reaction periods are short (often only a few seconds), the methods are laborious, and the precision of estimation of extent of hydrolysis per unit time is low. However, bio-assay methods may provide the nearest laboratory approach to the study of enzyme kinetics under physiologic conditions. The chemical methods are limited by their relative insensitivity to use of high substrate concentrations, but are capable of much greater precision. The flexibility and simplicity of chemical methods encouraged us to investigate the conditions under which they provide a satisfactory measure of the cholinesterase activity of blood.

A study of the cholinesterase activity of human blood preparations was reported¹ in which we were able to show that there are at least two enzymes possessing such activity in blood. One appears in the serum and the other in the cells, and the latter may be studied with solutions or suspensions of cells after centrifuging then washing. The effects of several variables affecting cholinesterase estimation techniques were also investigated. The present paper applies these studies to the problem of practical use of this type of assay and indicates the clinical situations in which cholinesterase determinations have given interesting results.

Over a wide range of conditions whole blood activity was found to be the sum of the separate activities of the cell and serum enzymes.¹ The cell enzyme activity markedly predominates over that of the serum as the substrate concentration is diminished to about that at which the enzymes must act in the body. The cell enzyme is inhibited by excess acetylcholine substrate, promoted by sodium ion in physiologic salt solution, and little affected by pH changes of the solution. The serum enzyme activity increases approximately with the substrate concentration up to 0.01 millimolar, and no inhibition is noted at higher concentrations.²⁻⁵ The serum enzyme has a pH optimum⁶ at about 8.0 and is inhibited only slightly by 0.85 per cent sodium chloride concentration.

*From the Laboratories of George Pinness, M.D., and Hyman Miller, M.D., Los Angeles.
Received for publication, January 29, 1940.

The influence of substrate concentration on rate and the inhibition of both enzymes by choline ion make it desirable to perform titrations at high substrate concentrations. The standard conditions that have been selected for the present titration method allow it to be readily applied to serum, cell, or whole blood samples with a high degree of precision.

METHOD

Blood for whole blood titrations is drawn from finger or ear prick into calibrated 0.2 ml. pipettes and immediately rinsed into 4.8 ml. of water containing 1:100,000 phenylmercuric acetate as a preservative. It may be stored on ice for a week or more before testing. For separated serum and cell titrations the technique already described¹ is satisfactory, or blood may be drawn as above, rinsed into 4.8 ml. of saline, centrifuged, and the cells washed once with saline, then laked in water to make 5 ml. The difference in sodium chloride content of the two fractions has only a slight effect on the serum activity (decrease of about 10 per cent). Possibly a better method would be to do all titrations at a final sodium chloride content of 0.85 per cent, but unfortunately the important influence of salts on the enzymes was not recognized before we had obtained our data on normal values of whole blood, serum, and cells.^{1,2} Since the values obtained can in any case have only comparative significance (see Discussion), it has not seemed worth while to repeat our work.

The titration is performed with the aid of a commercial glass electrode pH meter (Beckman model G). A test tube of 40 ml. capacity placed in a bath at 37° C., or jacketed and warmed with circulating water from a thermostat, serves as the reaction vessel. The contents are stirred by hand with a large glass bulb blown on the end of a piece of narrow tubing. The stirrer occupies 10 ml. of the volume. The electrodes are immersed in the reaction mixture to a depth of about one inch and kept there several minutes before taking readings in order to bring their contents to temperature equilibrium. It is necessary to use an excess of solid potassium chloride in the calomel half cell and to rerinse the liquid junction after temperature equilibrium is reached to keep the bridge solution saturated throughout. It is convenient to connect the electrodes to the pH meter by means of the special cable which is available. Standardized 0.02 normal sodium hydroxide is added as required from a 5 ml. burette with a capillary tip immersed in the reaction solution. A stock 0.02 molar acetylcholine solution is used which contains 5.46 Gm. of acetylcholine iodide in a liter of distilled water and is adjusted to pH 4.0 by the addition of 0.1 normal hydrochloric acid. This stock solution is kept in the dark in a tightly stoppered pyrex flask and is stable for three months or more.

The enzyme solution (5 ml.) and the acetylcholine iodide stock solution (20 ml.), separately warmed, are mixed in the reaction vessel and adjusted to pH 7.40. The burette is read and the pH is kept within 7.30 and 7.50 by small additions of standardized alkali. The time required for each 0.1 or 0.2 ml. increment of alkali is recorded to the nearest second. These should be constant within the reading errors. After about ten minutes the precision of estimation should be better than ± 2 per cent.

The amount of alkali used per twenty minutes⁸ is calculated, and a blank of 0.085 ml. is subtracted from this value to allow for the alkaline hydrolysis. The result is corrected for any pipette error to obtain the index of activity or "rate."

NORMAL VALUES

These data have been presented previously^{1, 7} and are collected here for convenient reference. In Tables I and II are shown the results of a number of individual determinations made on normal persons, *s* being the estimate of the standard deviation of their distribution.¹⁸ The data of Table I are grouped to permit an analysis of age or sex differences, and it is to be noted that no significant age or sex differences were found. In Table II repeated determinations on four normal persons are tabulated, and the data show that change of enzyme in a single person with time is confined to a range of variation only one-third of the variation from person to person.

In Table III is shown the distribution of enzyme of whole blood into serum and cell fractions and the ratio of serum to whole blood enzyme activities.

DISCUSSION

Perhaps more important than the method itself are two questions regarding the results which may be obtained: first, when may they be expected to be profitable? and second, what significance can be attributed to them? As an attempt to answer the first question, we have appended a summary of the literature on blood cholinesterase determinations of clinical and physiologic interest in the light of present knowledge of these enzymes. For the second, there are certain considerations that may assist the clinician in deciding what his results mean.

It is clear that present technique and knowledge do not permit physiologic interpretation of the results of blood or blood fraction assay. Other tissues are known to possess active enzymes, which have not been clearly characterized, and acetylcholine is readily diffusible. The only study of acetylcholine-cholinesterase physiology with which we are acquainted that seems reasonably free of critical objection is that of Glick,⁹ who worked, over a considerable range of conditions, with tissue from the superior cervical ganglion of the cat and confined his conclusions to the same organ. Significance of results must, therefore, be based on a comparison with normal values, or with a normal level established for the person studied in case it is desired to evaluate the results of therapy.

For the purpose of such comparison it has seemed to us that whole blood titrations have practically the same utility as blood fraction titrations. Under our conditions each enzyme contributes nearly the same share of the whole blood value. The probability of encountering compensatory changes in both enzymes seems negligible in view of the considerable differences in their behavior and of their demonstrated independence.

A second important consideration is occasioned by the relatively wide range of activities we, as well as others, found in ostensibly normal persons. The extremes in rates we found in about 100 assays of normal whole bloods were 0.500 to 1.068. If the rates are normally distributed about a mean of

0.76, with a standard deviation of 0.13, these limits would be expected to be equaled or exceeded about three times in 100 trials. Corresponding range limits for one time in 1,000, 100, and 20 are 0.33 to 1.19, 0.42 to 1.10, and 0.50 to 1.02, respectively.

These figures enable one to make an estimate of the possible significance of a single individual determination. For example, in assays on ten patients hospitalized for various conditions (unpublished data obtained through the cooperation of Dr. S. R. Baker of the Cedars of Lebanon Hospital, Los Angeles), the three lowest and the two highest values were 0.43 (coronary artery disease), 0.46 (spinal tuberculosis), 0.50 (subacute bacterial endocarditis), 1.04 (rheumatic heart disease), and 1.06 (hyperthyroidism). None of these can be considered individually significant or of diagnostic value, but they suggest that studies of these conditions might be of interest, and, indeed, in tuberculosis and in hyperthyroidism significant changes of activity have been demonstrated (see below) by comparing the average from a number of persons so afflicted with an average for normals. The range of variation of average values to be expected is much smaller than that for individual determinations and may be made as small as is desired by including a sufficient number of individuals in the groups. So far as we are aware, there is today no condition known for which the assay of blood cholinesterases can be expected to give individual results of consistent diagnostic value. It appears, however, that the possible prognostic value of individual determinations has not been explored.

CHOLINESTERASE IN DISEASE AND OTHER CONDITIONS

Ginsberg, Kohn, and Necheles¹⁰ reviewed much of the literature on blood cholinesterase determinations and came to the conclusion that a definite change had been demonstrated only in tuberculosis. However, it appears certain that the function of the (cholinergic) motor nerves is disturbed in myasthenia gravis. Walker¹¹ found that administration of cholinesterase inhibitors produces prompt but temporary relief of the symptoms of the disease. McGeorge¹² observed that the period of symptomatic improvement after giving prostigmine coincides with the period of decreased activity of the serum enzyme, as determined by the Stedman gasometric method. Fraser, McGeorge, and Murphy¹³ found that large doses of choline esters, including acetylcholine itself (given as the chloride), produced a delayed, prolonged period of relief, which they explained by postulating the utilization of some of the acetylcholine in formation of the acetylcholine precursor in the nervous tissue, since choline ion, with or without acetate, produced no such effect. Ingvarsson¹⁴ showed that a single large dose of acetylcholine iodide does not alter the activity of cholinesterase in whole blood, as determined by a modification of the Galehr and Plattner¹⁵ bio-assay method. Hall and Ettinger¹⁶ found that in dogs repeated large daily doses produced no change in serum enzyme.

With regard to the cholinesterases in the blood of myasthenic persons, there is a considerable divergence of results. Stedman and Russell¹⁷ demonstrated conclusively that, when estimated by Stedman's gasometric method, there is a significant decrease in the serum cholinesterase, while the corpuscle cholinesterase is normal in amount, as compared with normal individuals.

Fisher's "t" test¹⁸ applied to the difference between the arithmetic averages of the values of serum cholinesterase reported for 12 myasthenic and nine normal individuals, shows that a difference of this magnitude would have been obtained by accident only about one time in 50 if myasthenic persons were really no different in this respect from normal individuals (our own calculation). Two myasthenic persons, followed for a considerable period of time, showed a marked drop in blood cell cholinesterase values after spontaneous remissions of symptoms.

McGeorge's¹² observation that in three myasthenic persons the serum enzyme, measured by the Stedman titration method, was within the normal range, cannot be taken as a contradiction of the results of Stedman and Russell, since the values reported by the latter for normal and myasthenic persons overlapped. If Stedman and Russell's figures are representative, the number of individuals they measured is about as few as could be relied upon to show a significant difference. On the other hand, Hicks and MacKay¹⁹ found very large increases in serum cholinesterase in three myasthenic persons as compared with 20 normal persons. However, they failed to present data to show that the reliability and reproducibility of the bio-assay method which they used is adequate to demonstrate with certainty differences of the magnitude they found, especially since practically the whole of the discrimination depended upon differences in the rates of hydrolysis within the first five seconds of mixing the reagents. Furthermore, they used prostigmine to stop the reaction after it had proceeded for the desired time intervals, without presenting experimental justification for their assumption that the prostigmine acts practically instantaneously. Easson and Stedman²⁰ have shown that the reaction between this same inhibitor and an enzyme derived from horse serum by the Stedman and Stedman²¹ purification method requires several hours to reach equilibrium. Matthes²² also indicated that appreciable time was required to reach equilibrium in the reaction of eserine with whole blood.

Hicks and MacKay accounted for the difference between their results and those of Stedman and Russell by pointing out that their measurements were made under different conditions from those of Stedman and Russell. However, our experiments on the behavior of human serum enzyme with changes of pH and of substrate concentration show that this explanation is probably not valid, and that, should the observations of Hicks and MacKay be capable of critical verification, it will be a strong indication that the cholinesterase of myopathic sera differs qualitatively from that of normal serum.

Corkill and Ennor²³ made measurements of the total activity of whole blood of two myasthenic persons as compared with a group of normal persons using a bio-assay method to estimate the residual acetylcholine ion concentration after the enzyme had acted for twenty seconds and had been stopped by the addition of trichloroacetic acid (Galehr and Plattner,¹⁵ and Matthes²²). The myasthenic bloods fell well within the normal range of activity. This corroborates the findings of Stedman and Russell¹⁷ that the blood cell enzyme is within the normal range, since the measurements were made at a concentration of acetylcholine ion (approximately 0.0005 molar) for which we have found that serum enzyme contributes but little to the activity of whole blood.

Russell and Stedman²⁴ observed that the serum enzyme was low, in one patient with myotonia congenita, while the blood cell enzyme was normal in amount. Hicks and MacKay¹⁹ found five myotonia congenita patients to have a low serum enzyme. The figures available so far cannot be considered more than suggestive evidence of a changed cholinesterase situation in this condition.

In hyperthyroidism Antopol, Tuchman, and Selifrin²⁵ have shown that the cholinesterase of serum is markedly increased. A group of treated patients showed lower values. The same authors²⁶ have also published data showing serum values to be lowered in jaundice and biliary disease, and promise data showing decreased enzyme activity in several other conditions. They attribute the lowered values in jaundice to inhibition by bile salts.²⁷ However, their suggestion that the altered serum esterase may be related to nervous function ("sympathicotonicity or vagotonicity") must be considered at present as purely speculative, in view of the fact that no correlation between serum, blood cell, and tissue enzyme activity has been demonstrated. The same considerations apply to the observations of Tod and Jones^{28, 29} that the serum enzyme is significantly altered in certain mental states.

Investigators have been unable to find changes in the cholinesterases in a number of other disease conditions and physiologic states. Altenburger³⁰ found normal values in whole blood or spinal fluid of patients with epilepsy and with Parkinsonism, using a bio-assay method. We also found no change in titration values under our standard conditions of whole blood in a group of eight Parkinsonism patients under the care of Dr. E. Ziskind at the Los Angeles General Hospital (unpublished data). Hall and Lucas³¹ could find no correlation between serum cholinesterase (measured by a modification of the Stedman titration procedure) and age, sex, weight, exercise, fatigue, diet, blood pressure, resting heart rate, hemoglobin, and blood cell counts, or in women during menstruation or pregnancy in 40 normal and 162 hospital patients. Among the hospital patients they could find no correlation with the disease represented. Milhorat³² made a series of measurements of serum enzyme and arrived at similar conclusions. Obviously, these investigators may have overlooked significant alterations in total blood activity, because they did not include blood cell activity in their measurements.

We have been unable to find any shift in whole blood enzymes in allergic individuals or in asthmatic persons during attacks.⁷

We studied the effect of exercise upon cholinesterase content of the blood. It is known that both the motor nerve mechanism and the reflex vagus inhibition of the heart resulting from blood pressure rise act by acetylcholine mediation, and it seemed not unlikely that the increase of metabolism and blood pressure consequent to violent exercise might be reflected in changes of blood cholinesterases. Total blood cholinesterase activity measurements were made with our standard method before exercise, fifteen minutes after exercise (the time when blood lactic acid is maximal, according to Long and Lupton³³), and several hours later. The exercise was brief and sufficiently vigorous to more than double the heart rates in two normal adult males. No shifts beyond the limit of error of the method were found (unpublished).

The experiments of Manning, Lang, and Hall³⁴ on the inhibition of serum cholinesterase by eserine are interpreted by them as indicating that the ac-

cepted theory which attributes the physiologic action of eserine wholly to its inhibitory action on cholinesterase may be in error. This cannot be taken to prove their point, since Ammon and Voss³⁵ found that the cholinesterases of whole blood do not parallel serum enzyme in their inhibition by eserine. Even if experiments with whole blood enzymes were found to give similar results there would be no certainty that the enzyme of the tissues was likewise affected.

Dikshit and Mahal³⁶ demonstrated that the enzymes of whole blood are markedly affected by infection with *B. pestis* or vaccination with plague vaccine, which they interpret as a response to the toxemia and suggest that it may account for the muscular weakness of toxemias. They measured the enzymes both by a bio-assay method at low acetylcholine ion concentrations and by the Stedman gasometric procedure.³⁷ They found the agreement between the two methods to be improved by decreasing the substrate concentration in the latter method. From our work it would appear that this is a reflection of the increasingly predominant activity of the blood cell enzyme at lower substrate concentrations. The data suggest that the changes they observed were greater for the cell than the serum enzymes.

Other reports, whose expressed or implied conclusions depend on a parallelism in behavior between serum and blood cell or tissue enzymes, are the work of Glick and Antopol³⁸ on inhibition of cholinesterase activity by vitamin B₁, and of Minot³⁹ on the influence of toxic doses of guanidine on dog serum cholinesterase. Govaerts, Caubier, and van Dooren⁴⁰ concluded that varying degrees of individual sensitivity to acetylcholine were not dependent on differences in rate of destruction of the drug, because such differences could not be found in the plasmas. Ingvarsson's¹⁴ study with whole blood makes this conclusion appear more probable, but it should be noted that the conditions selected for esterase assay were far removed from those under which the enzyme acts *in vivo*, and may have prevented the detection of significant differences, even if one assumes that destruction in the blood stream is the only factor other than inequality of response that may affect sensitivity.

LABORATORY METHODS

GENERAL

IMPROVED INTUBATION TUBES FOR INSUFFLATION ANESTHESIA IN DOGS*

V. BROWN SCOTT, PH.D., M.D., AND HANS RUDOLPH
BLOOMINGTON, IND.

SINCE pneumothorax results in bilateral lung collapse in the dog, intrathoracic surgery must be performed under some form of intratracheal insufflation. The simplest method consists of periodic inflation of the lungs by blowing air ether intratracheally. A close-fitting intubation tube¹ or the introduction of a tracheal cannula is, however, required.

Hamilton, Woodbury, and Vogt² (1939) advocate, for intrathoracic operations, an interrupted blast of air via a small tracheal catheter. This catheter carries a balloon, inflated through an opening in the catheter above its terminal one, which raises the pressure in the trachea during each blast. This method is said to be an improvement over other methods.

Livingstone and Hrdina³ (1930) developed a "modified Meltzer apparatus" which has been used successfully in their laboratory for many years. This simple apparatus delivers ether air at low pressures (compressed air passes through an ether "bottle") to the bifurcation of the dog's trachea via an urethral catheter (No. 16 French). Desired inflation of the lungs is accomplished by impeding the exhaust of gases through the trachea. This is accomplished by a modified Kunde mask into which the dog's muzzle is introduced through a perforation in a tight-fitting rubber dam. The other end of the mask (metal can) has two openings; one opening allows the passage of the insufflating catheter, the other is connected with a tube which leads the exhaust gases into an 8 liter water bottle. The catheter passes intrabuccally through a metal airway.

We have had occasion to use the above apparatus repeatedly in intrathoracic operations. The method has proved essentially satisfactory since one can easily maintain *apnea vagi* by moderate distention of the lungs. No untoward results of this anesthesia have been encountered, and the motionless thorax is a distinct advantage in these operations. We have found, however, disadvantages in the use of the Kunde mask, flexible catheter, and airway used by Livingstone and Hrdina.

Ether anesthesia for most operations in the dog is, we believe, given most satisfactorily by a tight-fitting metal intubation tube¹ which is introduced into the trachea through the larynx. A set of six twelve-inch tubes, ranging from $\frac{3}{4}$ to $\frac{7}{16}$ inches (outside diameter), will be satisfactory for dogs weighing less

*From the Department of Physiology, Indiana University School of Medicine, Bloomington.
Received for publication, February 26, 1940.

than 20 kg. Such tubes can be equipped with a beveled tip (to facilitate intubation) and nickel or chrome plated. Such a tube connected with an ordinary ether "bottle" by a short rubber tube eliminates the bulky Kunde mask and has proved entirely satisfactory. Atropine, preoperatively, is unnecessary.

Satisfactory anesthesia with the metal tubes led us to devise intubation tubes which are used for intratracheal insufflation anesthesia and replace the Kunde mask, metal airway, and long catheter used by Livingstone and Hrdina. This not only eliminates bulky apparatus but makes intubation much simpler.

Fig. 1.

APPARATUS

The intubation tubes (Fig. 1) consist of six nickel-plated brass tubes, 12 inches long (standard seamless brass tubing of outside diameters: $\frac{3}{4}$, $\frac{11}{16}$, $\frac{5}{8}$, $\frac{9}{16}$, $\frac{1}{2}$, $\frac{7}{16}$ inches). A smaller tube ($\frac{3}{16}$ to $\frac{5}{16}$ inches, outside diameter), $13\frac{1}{2}$ inches long (A-F), is fixed inside the larger tube with A (upper end) protruding

1 inch while *F* (lower end) extends $\frac{3}{4}$ inch below the beveled tip *E*. The outer tube is closed completely about the smaller tube at *B*. Side tube *C* is closed but *D* communicates only with the space between the long inner and outer tubes. The lower end of the outer tube is fitted with a beveled tip *E* (see Fig. 2) which leaves an opening between the tubes. A 3 inch rubber tube *G* is attached to the inside tube *F*.

Fig. 2.

METHOD

One hour after administration of morphine sulfate (1 mg. per kilogram) the dog is anesthetized with ether. Under deep anesthesia the lower end of the intubation tube is introduced through the larynx on *inspiration* (the tube selected should fit the trachea snugly). The intubation tube is passed caudad so that the tip of rubber tube *G* lies just above the bifurcation of the trachea. Tube *A* is connected with the compressed air-ether source, and *D* is connected with the exhaust tube leading to the water bottle. The dog's jaws are bound tightly about the intubation tube, the bandage being carried around side tubes *C* and *D* to prevent slipping.

By this device an air-ether mixture can be blown down tube *A* under 2 to 4 cm. Hg pressure and carried to 1 cm. above the bifurcation of the trachea by tube *G*. Exhaust gases pass between the inner and outer tubes and out through *D*. The latter is connected with a metal tube which can be submerged (thus regulating the exhaust pressure) to the desired level. Pulmonary inflation to secure *apnea vagi* can be obtained easily by raising the exhaust pressure. This manipulation allows one to abolish all thoracic movement. Restoration of "negative" intrathoracic pressure is accomplished by lung distention at time of closure of the thoracotomy.

SUMMARY

An intubation tube for use with positive pressure apparatus for anesthesia in dogs undergoing intrathoracic surgery, together with its method of use, is described.

A SIMPLE AND COMPACT ERGOGRAPII FOR STUDENT USE*

G. L. MAISON AND A. G. BROEKER, ST. LOUIS, MO.

THE instrument to be described has several advantages over ergographs in common use at present. It is readily stored, having over-all dimensions of 18 by 6½ by 4 inches. It permits recording of excursions on drum. It records on an automatic counter the total distance through which force is applied. It can be used with unlimited stroke, or the length of stroke can be fixed so that uniform strokes are made. Its principal disadvantage is that experiments demonstrating the effect of varying the load on muscular ability can be done only if several machines of different inherent resistance are available for the student to use. The considerable variety of experiments which can be performed with fixed load make the machine useful despite this disadvantage.

The Ergograph.—Fig. 1A shows a simple sketch of the machine with fingers in place ready for use. Note that the muscle used is the *extensor digitorum communis*. A consideration of the anatomy of the forearm and hand will show that with the metacarpus firmly fixed to the board by strap (*a* in Fig. 1A) no other muscle can apply force to the work.

The fingers are attached to the instrument by means of a rawhide thong. Fig. 1A shows the instrument seen from the side (sideboard removed) with the fingers in place in the thong (*b*). Fore, middle, and ring fingers are inserted. Connection is made from the thong by means of wire to the furthest point of a metal quarter circle (*c* in Fig. 1A and B). This piece is made of sheet brass 0.036 inch thick, 2 inches wide, and 4 inches long, bent to a right angle (Fig. 2A) to which is soldered a piece of the same sheet brass curved to a radius of curvature 2 inches. The result seen from the side is a quarter circle (Fig. 2B). The wire is attached at the uppermost end of the curved sheet. The center of the quarter circle is now soldered to a brass rod 6 inches long and 3/16 inch in diameter at about its center (Fig. 2C). This forms the axis to which force is applied. The ends of this rod are drilled out to receive a piece of hardened steel rod 1/8 inch in diameter which is allowed to project from the end of the rod to act as a bearing (Fig. 2D). These bear on holes of proper size drilled in side pieces of brass rectangular bar 1/8 by 3/4 inch which are recessed and screwed to the sides of the top board of the ergograph. The load factor or resistance to the movement of the axle is supplied by a coiled music wire spring whose lumen diameter is about 1/4 inch.† It is slipped over the axle and anchored to the brass quarter circle on one end, and to the bearing plate on the other (*d* in Fig. 1B). Friction between the axle and the spring is prevented by having the lumen diameter of the spring greater than the diameter of the axle and also by soldering a small brass collar (*a* in Fig. 2E) to the bearing plate within which the axle fits and on the outside of which the spring rides. The resistance

*From the Department of Physiology, St. Louis University School of Medicine.
Received for publication, March 6, 1910.

†Music wire 0.048 inch in diameter fashioned into a spring of 1/4 inch inside diameter having 23 turns in 2 inches length tightened by one full turn before being anchored produces about 100 Gm. tension, which is a good resistance for untrained *extensor digitorum communis* muscles.

to turning of the axle will depend on the strength of the spring wire used and on the number of turns made on it before it is anchored. The finger thong is attached around the circle so that the force will always be applied at a fixed distance from the axis.

Seen from side, as if side board were transparent

Seen from above, as if top board were transparent

Fig. 1.

The same principle is used in activating the meter to count the number of centimeters through which the force is applied. A small hole is drilled in the anterior end of the curved brass plate and a cord is fixed in this hole (Fig. 2F). The cord runs backward under the arm board to a spindle to which it is anchored after several turns. The spindle is 5 cm. in circumference and 1.5 inches long. It is held up on one side by a brass bearing and on the other by the shaft of a Veeder rotary ratchet counter (type Q13) to which the spindle is fixed. Each rotation of the spindle will turn the counter through 10 units and will imply that force has been applied through 5 cm. Thus each unit on the counter is 0.5 cm. Since turning the axle pulls the cord over an arc at a constant distance from the axis of rotation of the axle, the distance indicated by the counter will be correct.

After a movement the axle will be returned to normal position by the spring. The cord must be returned by a separate mechanism. This is accomplished by applying a second cord to the spindle which after several turns passes forward under the arm board to a spring wheel (Fig. 2G) which exerts a tension tending to unwind the cord from the spindle. Thus when the axle is turned, the cord is wound off the left side of the spindle, activating the counter. Simultaneously, the cord is also wound on the right side of the spindle from the spring wheel. After the force is released, the spring returns the axle to place, freeing the axle cord to the spindle. The tension of the spring wheel brings the cord back from the spindle onto the wheel and thus returns the axle cord to the spindle. The counter is prevented from backward rotation by its inherent ratchet.

Fig. 2.

The ergograph is designed to record on drum through air transmission to a tambour with fall-away lever. The hardened steel bearing peg inserted in the shaft on the side opposite the spring is made long enough to extend $\frac{1}{2}$ inch beyond the bearing plate (see Fig. 2D and E). To this peg is fixed an eccentric cog $\frac{1}{2}$ inch in diameter and $\frac{1}{4}$ inch thick (a in Fig. 2H). Below this cog, and fixed to the bearing plate, is a brass trough (b in Fig. 2E and H) which lies $\frac{1}{8}$ inch below the base of the eccentric cog when the axle is twisted to its maximum stroke. The trough is $\frac{5}{16}$ inch wide. A rubber tube is inserted between the cog and trough. At the posterior end of the trough there is soldered to the brass plate a brass rod projection (c in Fig. 2H) upon which the rubber tubing can be

fixed so that it is firmly held and prevented from leaking air. The other end of the rubber tube is attached to the tambour. In actual use the strokes upon the drum can be readily translated into centimeters of excursion by calibrating the extent of excursion per given distance as measured on the counter.

For certain applications it is desirable to make the ergograph strokes uniform. This is readily accomplished by arranging contacts so that a buzzer sounds when the stroke reaches a given distance. Fig. 1C shows contacts and buzzer installed. A brass rod $\frac{1}{2}$ by $\frac{1}{4}$ by $\frac{1}{8}$ inch is soldered to the outer edge of one flange of the spring wheel so that it projects radially (*a* in Fig. 1C). To the undersurface of the arm board there is affixed a metal bar (*b*) which acts as a base for a swing lever (*c*) of brass 0.025 by 0.125 by 4.0 inch. The swing lever is prevented from downward swing by crimping its end behind the fulcrum, and prevented from upward swing by a simple spring wire attached to the fulcrum. Thus it is held horizontal $\frac{1}{2}$ inch below the undersurface of the sideboard. An electric door buzzer (*d*) is fixed to one of the sideboards. A dry cell is connected to one pole of the buzzer and to the base of the spring wheel. The second buzzer pole is then connected to the swing lever holder.

When the fingers are extended, the spring wheel is rotated until the projecting contact strikes the swing lever. The circuit is then completed, ringing the buzzer. The subject pulls until the buzzer sounds, relaxes, and pulls again, making uniform strokes. If the buzzer is disconnected, or if stroke is continued despite the buzzing, nothing prevents the wheel from rotating as the spring of the swing lever readily gives. Thus the buzzer can be left out of operation by simply disconnecting the battery.

The advantage of stroke uniformity is that it establishes a neat end point to call fatigue. Fatigue can be defined as that condition of the person in which he cannot make a stroke of this length in the given time interval.

Some Applications of the Ergograph for Student Use.—

1. Demonstration of *treppe*—human fatigue curves.
2. Comparison of work a muscle can do circulated with the work it can do when ischemic.
3. Effect of rate of contractions on total work ability of muscle, (a) circulated or (b) ischemic.
4. Effect of motivation on muscular ability—comparison of work output ringing buzzer with work output without buzzer.
5. Effect of massage on muscular ability.
6. Effect of fatigue of other muscles on the work of an unused muscle.
7. Effect of ischemic work on the blood pressure and heart rate (reflex of Alam and Smirk).
8. The character and properties of ischemic pain.

(All these experiments except No. 4 can be done with or without the buzzer.)

Calculation of the Work Done on the Ergograph.—The resistance against which the force works is that of a spring. This means that the resistance increases gradually throughout the stroke. The resistance can be calibrated by hanging weights on the finger thong with the ergograph suspended in a vertical position (as in Fig. 2I). Gravity acting on the weights will overcome the resistance of the spring. If gravity acting on a weight of 1,100 Gm. moved the counter 4 units (2.0 cm.), then $1,100 \times 2.0 = 2,200$ gram centimeters of work

must be expended every time a stroke 2.0 cm. long is made. On a particular machine the following calibration was obtained:

Weight Suspended	Average Movement Recorded
1,100 Gm.	1.3 cm.
1,150 Gm.	2.8 cm.
1,200 Gm.	3.5 cm.
1,250 Gm.	4.5 cm.
1,300 Gm.	6.8 cm.
1,350 Gm.	9.0 cm.

This implied that a stroke of 6.8 cm. required the same work as would have been required if a constant load of 1,300 Gm. had been used, and that $6.8 \times 1,300 = 8,840$ gram centimeters of work were required to make the stroke of this length. For student use a simple method of calculation was desired. With the buzzer in use there was no difficulty, since all strokes were uniform and gravitational calibration gave the uniform load equivalent of this stroke. Thus the work was calculated as the product of distance times this equivalent. When the buzzer was not being used and the length of the stroke varied widely, it was questionable whether a gravitational equivalent based on average stroke length would be sufficiently accurate. The average stroke length in any given work bout was readily obtained by dividing the distance recorded on the counter by the number of strokes made by the subject. The number of strokes can be counted as made or from the kymogram. Several methods of calculation suggested themselves and were checked on twenty different records made on various experimental procedures.

Method 1. From the twenty different trials the average stroke for all trials was 6.4 cm. Referring back to the calibration and interpolating, the uniform load equivalent was about 1,290 Gm. Multiplying the distance factor in each bout of work by 1,290 then approximated the work in gram centimeters.

Method 2. Another possibility was to use the average stroke for each particular bout of work. In the twenty different trials the average stroke varied from 5.1 to 7.8. The distance in the bout of 5.1 cm. average stroke was multiplied by 1,260 Gm. to obtain the work; the distance in the 7.8 bout was multiplied by 1,320 Gm. to obtain the work.

Validification of Method.—Both methods 1 and 2 arrive at approximations, and while it is obvious that the work results by the two methods can show no greater variation in these twenty records than 3 parts in 129, one has no idea how far the result by either method is from the true work done.

Method 3. The work done in each bout was determined accurately as follows: Before each of the twenty work bouts a calibration of centimeters of stroke against millimeters of tambour excursion was made. This is rendered easy by the automatic counter, since by watching the counter, strokes of 1 cm., 2 cm., 3 cm., etc., can be made. After the record was fixed, each stroke was translated from millimeters to centimeters so that an incidence record resulted. Table I shows the incidence of different strokes in a particular record. It can be seen that the strokes varied from 2.25 to 8.0 cm. in length. Referring back to gravitational calibration, the gravity equivalent of each one of these strokes was obtained as seen in the fourth column of Table I. Now the centimeter equivalent was multiplied by the incidence of such strokes, and the product was

multiplied by the gravity equivalent of this length of stroke. The sum of these results gave the work done. The work calculated by methods 1 and 2 in this case was $498 \times 1,290 = 643,000$ (1) and $498 \times 1,295 = 646,000$ (2).

TABLE I
CALCULATION OF WORK BY INDIVIDUAL STROKES
(Incidence From Tambour Record)

MM.	CENTIMETER EQUIVALENT		INCIDENCE		GRAVITATIONAL EQUIVALENT		
11	8.0	x	2	x	1,325	=	21,200
10	7.4	x	21	x	1,310	=	204,000
9	6.75	x	34	x	1,300	=	298,000
8	6.25	x	9	x	1,290	=	72,500
7	5.75	x	1	x	1,275	=	7,300
6	5.10	x	1	x	1,260	=	6,400
5	4.5	x	3	x	1,250	=	16,900
4	4.0	x	2	x	1,225	=	9,800
3	3.4	x	2	x	1,200	=	8,200
2	2.25	x	2	x	1,125	=	5,100
							649,400

One may wonder whether the ability to measure tambour strokes on a record is good enough to warrant calling method 3 accurate. There is a ready check on the accuracy of the measurement as follows: If in Table I the centimeter equivalents are multiplied by the incidence alone and all the products are summed, the result is the total distance through which the force was applied; in this case the sum was 500.9 cm. But the counter also added up the total distance during the work bout as 498 cm. Thus the measurement is checked.

This procedure was carried out with each of the twenty records, and the percentage error of work as calculated by methods 1 and 2 from method 3 taken as accurate varied from -3.9 per cent to +2.1 per cent for method 1; from -3.1 per cent to +1.7 per cent for method 2. We conclude that the error involved by either method 1 or 2 is small; that method 2 is somewhat less subject to error than method 1.

For student use we furnish a weight calibration with each instrument and instruct the student to use method 2. After the instrument is assembled it requires a week or two for the spring to take its set. The force of the spring seems to remain quite constant once the set is taken. Probably gravitational calibration at least once a year will be necessary.

SUMMARY

A student ergograph for human extensor digitorum communis has been described. Its over-all dimensions are 18 by $6\frac{1}{2}$ by 4 inches. It is economical to construct. It permits limitation of stroke length so that fatigue can be more sharply defined as an end point. A list of experiments to which it can readily be applied is given. Methods available for calculation of the work done on the machine are discussed and validated. The portability of the ergograph recommends it for clinical use in following the work ability of patients under treatment for Addison's disease, and myasthenia of any other origin in which the various muscles are fairly uniformly affected.

THE USE OF A SINGLE GUINEA PIG FOR VIRULENCE TESTING*

MARGARET BEATTIE, M.A., GR.P.H., BERKELEY, CALIF.

IN A PREVIOUS study¹ it was demonstrated that the use of a single rabbit for virulence testing by means of the coincident intracutaneous injection of a test and a control suspension of *C. diphtheria* culture mixed with antitoxin (instead of the parallel injection of the culture suspension into an unprotected and antitoxin protected animal) so enhanced the inherent variability of rabbit reactivity to diphtheria toxin as to yield falsely negative reactions in tests with known pure cultures of *C. diphtheriae*. This modification of the traditional technique was introduced by Fraser, Halpern, and Roy² as an economical way to test the large number of cultures involved in research or survey investigations. Only under extraordinary circumstances would a public health laboratory have so many tests to perform at one time or have rabbits available for this purpose. In such a laboratory the economy involved in the use of a single animal for a few tests would be desirable. In health department laboratories it is important to discover immediately whether organisms, with morphology characteristic of *C. diphtheriae*, when isolated from the throats of carriers, recovered patients, or immunized contacts, are virulent. The infectiousness of the immunized child whose throat lesion yields organisms morphologically resembling diphtheria bacilli is also important to health authorities.

At the time the experiments on rabbits were done, a few guinea pigs were tested by this technique. These tests indicated that while the guinea pig was less apt to vary in reactivity to the injections than the rabbit, some differences in reaction occurred in animals injected with control suspensions. In order to limit the effect of antitoxin, the number of tests to be placed on each animal was reduced from eight to four. The amount of antitoxin in the control suspension was decreased to what appeared to be the least amount for neutralization of toxin.

Cultures.—Four cultures were selected from the sixteen which had been used on rabbits. One (No. 75), a gravis strain, was chosen as a control culture because it had reacted positively on all rabbits and guinea pigs. Two intermediate strains (Nos. 133 and 198) which had frequently yielded inconclusive or negative reactions were included as test strains. The fourth test culture was a mitis strain (No. 206) which had occasionally induced negative or inconclusive reactions on rabbits.

Test Inoculum.—In order to obtain a sufficient amount of culture suspension, several slopes of Loeffler's medium were inoculated with each test culture. This was accomplished by delivering with a pipette a saline suspension made

*From the Department of Hygiene, University of California, Berkeley.

Received for publication, March 11, 1940.

from the growth on a Loeffler's slant onto the surface of each of several slopes. Complete seeding of the surface was accomplished by rotating the inoculum over the surface of the slopes before placing the tubes in the incubator. After forty-eight hours' incubation the growth on each slope was suspended in 2 c.c. of Stone's suspending solution.³ A stained smear from each test culture was examined to check the presence of morphologically typical bacilli in pure culture. Subcultures were made from one tube of each set of cultures to be certain the material was viable. Because of the color and consistency of the suspending solution, only a rough estimation of the relative opacity of the suspensions could be made.

Control Inoculum.—To each cubic centimeter of suspension prepared as described above, 0.1 c.c. of antitoxin, containing approximately 100 units, was added. The suspension was well mixed and allowed to stand at room temperature for at least half an hour before being injected. This amount of antitoxin was evidently near the minimum because very slight necrotic reactions were occasionally observed.

Animals.—Of 129 guinea pigs all were white females except eleven which were white males. All animals were fully mature and weighed more than 400 Gm. though they varied considerably in weight, size, age, and skin texture.

THE EXPERIMENT

Five groups of from twelve to forty animals were tested within a three months' period. In each experiment the sex and size of the animals were considered in selecting those to be compared as test and control animals. Test animals received intracutaneous injections of both test and control culture suspensions coincidentally. Control animals received injections of test culture suspensions only. Each animal received the same culture suspension in the same skin area for any experiment. One-tenth cubic centimeter of inoculum was injected intracutaneously into the shaven skin on the side of guinea pigs. The control animals received 1,000 units of antitoxin five hours after the tests were placed. Both test and control animals received 1,000 units of antitoxin twenty to twenty-six hours after the tests had been placed. The reactions were observed at twenty-four-hour intervals for three days. Reactions were designated as positive when an area of necrosis resulting in a scab more than 4 mm. in diameter was formed; inconclusive when a small scab (less than 4 mm.) was observed; and as negative when no area of necrosis was noted.

RESULTS AND DISCUSSION

One hundred and twenty-nine guinea pigs were injected. Sixty-five guinea pigs (test animals) were injected with both test and control culture suspensions. Sixty-four guinea pigs (control animals) received injections of test suspension alone. Only one culture (No. 198) induced inconclusive and negative reactions which indicated variation of reactivity in the guinea pigs tested.

Of the sixty-five test animals, 53 reacted positively to all injections. Five animals had inconclusive reactions and seven gave negative reactions at the site of the injection of one test culture (No. 198).

Sixty-three of the 64 control animals yielded positive reactions to all test injections. One animal, on which all reactions developed slowly and were small, showed an inconclusive reaction at the site of injection of one test culture suspension (No. 198).

Differences in time and rate of development and size of lesion were apparent in different animals, but, on the whole, the lesions on the test animals were obviously smaller, particularly the lesions induced by the culture (No. 198) which was the sensitive indicator of any variation in guinea pig reactivity. The diameter of the scabs was measured in one group of 40 animals in order to verify this apparent difference. Culture No. 198 on the control group of guinea pigs induced scabs whose average diameter measured only 0.2 mm. less than the smallest average scab measurement of the three other cultures tested, whereas in the test series the scabs induced by this culture had an average measurement 2.0 mm. less in diameter than the other cultures. These measurements completely confirmed the observation that the reactions were larger on the animals of the control series.

It is evident that the use of control inocula containing antitoxin modifies the reaction on single animals injected intracutaneously for diphtheria virulence testing so as to render erroneous results. It might be possible to limit the application of the technique to one or two tests by determining the maximum amount of antitoxin which could be safely used, but this would involve the use of antitoxin closely measured for maximum as well as for minimum unit content. Such antitoxin is not available in the public health laboratory. A single animal can be utilized by repeating the injection of the test suspension in another skin area of the animal converted into a control by the intravenous injection of antitoxin five hours after the test injections are placed. This modification of technique was described by Fraser and Weld in 1926.⁴ The time interval and the labor involved in repetition of the injections frequently complicates the schedule so as to render the test inconvenient in a public health laboratory.

CONCLUSIONS

Guinea pigs vary only slightly and much less than do rabbits in their reactivity to the injection of cultures of *C. diphtheriae*. The coincident intracutaneous injection of a control mixture of culture and antitoxin which permits the use of a single guinea pig for several tests cannot be recommended since false negative or inconclusive reactions may occur.

ON THE PRESERVATION OF SPECIFIC ANTI-M AND ANTI-N AGGLUTININS WITH TOLUOL*

PHILIP LEVINE, M.A., M.D., NEWARK, N. J.

IT IS well known that antisera, when preserved in the cold in the filtered state, retain their antibody content almost undiminished over a period of several years. For the production of diagnostic anti-M and anti-N reagents, it is necessary to remove the species-specific agglutinins by absorption with suitable bloods lacking the factors in question. For this purpose, the serum in a dilution of 1:15, 1:20, or higher is absorbed for one-half to one hour with one-half its volume of washed blood sediment. Generally, one absorption suffices to remove the species-specific agglutinins, but occasionally a second treatment, with perhaps a smaller quantity of blood, may be required. While these manipulations can be carried out under sterile conditions, this is not convenient, and consequently the diagnostic fluids become unsuitable for use after a few days in the ice chest because of bacterial contamination. Once potent diagnostic reagents are prepared, it is of considerable advantage to preserve them for future use on account of the large quantity of selected blood necessary for the absorption and the time and effort required for the numerous manipulations.

A number of years ago I¹ tested a few preservatives and observed that the addition of 1 drop of toluol per cubic centimeter of diagnostic fluid, stoppered and sealed with paraffin, gave very good results. Tests with diagnostic fluids preserved in this manner for a period of six to twelve months have invariably given unequivocal results, so that the tests always gave a sharp distinction between bloods possessing and bloods lacking the agglutinogens in question. Those rare bloods reacting weakly with potent diagnostic fluids, freshly prepared, were invariably agglutinated by the preserved fluids. At no time in an active, continued experience, extending over a period of ten years with the use of fluids preserved in this manner, were any difficulties encountered in the diagnosis of the M and N factors.

In a study of various preservatives of diagnostic fluids, Boyd² comes to the conclusion that there are a number of preservatives (such as brilliant green or acriflavine) which are preferable to toluol. However, Boyd made no tests with toluol preserved fluids before four and one-half years elapsed, at which time all activity had disappeared.

For this reason, I made tests with anti-M and anti-N diagnostic fluids preserved with toluol for a period of thirty-two months. These were the only fluids available to test the efficacy of the preservative, but it seems to me that a preserved diagnostic fluid still potent after an interval of thirty-two months in the ice chest is certainly properly preserved.

*From the Division of Laboratories, Newark Beth Israel Hospital, Newark.
Received for publication, March 13, 1940.

Actually, these specific diagnostic reagents were found to give potent reactions that compared favorably with those obtained in simultaneous tests with freshly prepared reagents from the same antisera (Tables I, II, III).

TABLE I

DIAGNOSTIC FLUID	GROUP	O	A	A	A	A	A	B	O	A	A
	TYPE	M	M	M	MN	MN	MN	MN	N	N	N
Anti-M (1)		++++	++++	++++	++++	++++	++++	++++	0	0	0
Anti-M (2)		++++	++++	++++	++++	++++	++++	++++	0	0	0
Anti-N (3)		0	0	0	±	±	±	±	++++	++++	++++
Anti-N (4)		0	0	0	++	++	++	++	++++	++++	++++

The plus signs indicate varying degrees of agglutination.

(1) Prepared from serum 136, diluted 1:15, and preserved with toluol on July 3, 1937.

(2) Freshly prepared from serum 136, diluted 1:15.

(3) Prepared from serum 52, diluted 1:20, and preserved with toluol on July 3, 1937.

(4) Freshly prepared from serum 52, diluted 1:20.

TABLE II

TITRATION OF THE ANTI-M FLUIDS						
		1:6	1:12	1:24	1:48	1:96
Anti-M No. 136 preserved for 32 months	(1) OM	++++	±	+	tr	0
	(2) AM	++++	+++	+	0	0
	(3) OMN	++++	+++	+	0	0
	(4) AMN	++++	±	±	0	0
Anti-M No. 136 fresh	(1) OM	++++	±	+	0	0
	(2) AM	++±	+	0	0	0
	(3) OMN	++±	±	tr	0	0
	(4) AMN	±	+	0	0	0

tr. indicates trace.

TABLE III

TITRATION OF THE ANTI-N FLUIDS					
		1:6	1:12	1:24	1:48
Anti-N No. 52 preserved for 32 months	(1) ON	±	+	tr	0
	(2) AN	±	+	f.tr.	0
	(3) OMN	±	0	0	0
	(4) AMN	+	±	0	0
Anti-N No. 52 fresh	(1) ON	++±	+	f.tr.	0
	(2) AN	±	+	tr	0
	(3) OMN	+	tr	0	0
	(4) AMN	±	+	0	0

tr. indicates trace; f.tr., faint trace.

It is clear that the anti-M diagnostic fluids, preserved with toluol for thirty-two months, is just as active as the fluid freshly prepared from the same serum; the preserved anti-N fluid gave reactions which were only slightly less intense than those with the freshly prepared fluid. Titrations of the fresh and preserved anti-M fluid gave results which indicate that the preserved fluid is, indeed, somewhat stronger than the freshly prepared reagent. Similar slight differences of behavior of the two diagnostic fluids were observed in testing with other bloods, not recorded in Table II. The titration of the anti-N fluids gave results which confirm those of Table I, namely, a slightly greater activity on the part of the freshly prepared fluid.

Obviously, there are other suitable chemical preservatives for specific anti-M and anti-N reagents, as has been shown by Boyd. Another suitable procedure would seem to be drying with some such technique as the Flosdorf-Mudd apparatus. In any event, the results here reported indicate that toluol may be just as efficient a preservative as, for instance, aeriflavine, especially since Boyd's anti-M fluid No. 887, preserved for twenty-two months with aeriflavine, already showed a considerable diminution in activity.

Addendum: Retest of the same diagnostic fluids on January 20, 1941, i.e., after preservation of three and one-half years, showed no loss of activity in the anti-M reagent. The anti-N reagent suffered a drop of titer, distinct reactions obtainable at a dilution of 1:6 instead of 1:12; tested in the undiluted state, the anti-N diagnostic fluid gave clear-cut differentiation.

A SIMPLE, INEXPENSIVE, VERTICAL ILLUMINATOR FOR THE STUDENT MICROSCOPE*

ALRICK B. HERTZMAN, PH.D., ST. LOUIS, MO.

THE need for vertical illumination for examining human skin capillaries and minute vessels in the frog in the student laboratory directed attention to the possibility of using for this purpose the very effective pencil flashlight bulb known as Mazda 222 (operating on 2.2 volts). A simple, flexible, convenient, and effective mounting was provided with a dial socket, screw type (costing four cents), carried by a copper wire, 10 inches in length and $\frac{1}{8}$ or $\frac{1}{4}$ inch in diameter. This in turn was clamped to the ring stand. The beam of light could then be directed to the vascular area to be observed. The arrangement can be brought close enough to provide enough light for observation of the minute vessels unless high magnifications are required. When strong illumination is desired for microphotography, the bulb may be operated momentarily above its rated voltage by inserting a single pole double throw toggle switch in the lead to the bulb and providing a source of slightly higher voltage.

The current source may be dry cells, but in the student laboratory we operate a group of bulbs on one filament transformer supplying a.c. at 2.5 volts. A short piece of resistance wire in the lead to the bulb reduces the voltage to the correct value. When the bulbs are operated below their rated voltage, they last twenty-four hours or more in continuous operation.

We placed thirty of these illuminators in the student laboratory at a cost of less than ten dollars. They proved very satisfactory for student study of the minute vessels. Other uses will suggest themselves.

THE USE OF DIAPHANE FOR MOUNTING GIEMSA TYPE PREPARATIONS*

FREDERICK COULSTON, M.A., SYRACUSE, N. Y.

IN LABORATORIES where Romanowsky-type stains are used, it has always been a problem to find a satisfactory as well as permanent mounting medium. This is especially true of those laboratories where malaria research is done. For here the routine method of staining the parasites invariably consists of the use of one of the better Romanowsky stains, such as Giemsa's, MacNeal's tetrachrome, or Wright's.

In general, three types of preparations are used; namely, blood smears, and smears and sections prepared by dehydration. When these are mounted in balsam, the stain almost always fades considerably within a few months or a year. This fading is usually found in the region of the smear or sections farthest from the edge of the cover slip, leaving a rim of fairly well-stained material. The reason advanced for this gradual destaining process is that the α and β abietinolic acid in the balsam gradually oxidizes, thus changing the pH of the medium. And since the Romanowsky stains work best in an alkaline state, this causes them to fade.

Many alterations in the balsam have been suggested to counteract this tendency toward acidity. In Lee's¹ *Vade Mecum* (1928, p. 231) a method of making neutral balsam is given which consists essentially of mixing the balsam crystals with an equal amount of sodium bicarbonate. Scott² (1911) recommends placing a piece of marble in the balsam bottle and protecting the bottle from light. A similar suggestion is made by Guyer³ (1936, p. 129). This works satisfactorily for awhile but fading eventually occurs. Cannon and Talinferro⁴ (1931) mounted sections in balsam without cover slips, stating that this prevented rapid decolorization. Huff and Bloom⁵ (1935) used a petrol-ether soluble fraction of crude dammar dissolved in xylene as a mounting medium. Kingsley⁶ (1937) recommends keeping stained megakaryocytes and platelets in sections mounted in neutral xylene dammar away from light. Lee (p. 503) suggests mounting Giemsa-stained sections in cedar oil rather than in balsam, since in the latter the colors fade more rapidly.

In 1927 Wright⁷ showed that euparal was an excellent mounting medium for blood smears stained with the many Romanowsky-type stains. Slides so mounted did not fade for over six years. Euparal was introduced by Gilson⁸ (1906) who stated it was a mixture of eucalyptol, paraldehyde, and eamsal. A similar American product is sold by some supply houses under the name of diaphane. This product is said to contain euparal, ether, gummed sandarac, and paraldehyde. Shepherd⁹ (1918) presented the formula of a substitute for euparal which he claimed was in all respects similar to it. Both euparal and diaphane have a refractive index of 1.483. Each is available in a colorless and a green form. The latter contains a copper salt, the color of which is said to

*From the Department of Zoology, Syracuse University, Syracuse.
Received for publication, March 16, 1940.

intensify hematoxylin stains. The colorless diaphane is the proper one to use for mounting Romanowsky-type stained preparations. Histologic comparisons of diaphane and euparal indicate that they are identical in properties. Therefore, in this paper when reference is made to diaphane, it is implied that the same is true of euparal.

Diaphane is superior to balsam in many respects, and especially in that it is a nonoxidant and is neutral to all stains. It also has a lower index of refraction, enabling observation of objects totally invisible in balsam or dammar. Most materials may be mounted in it directly from 95 per cent alcohol.

Recently, Groat¹⁰ (1939) described two new cycloparaffin mounting media, commercially called Nevillite V and No. 1. These substances are similar to balsam and are soluble in toluene and xylene. They are said to be superior to balsam in that they do not become acid with age. However, they have higher refractive indices (Nevillite V, 1.544; Nevillite No. 1, 1.567) than balsam (1.535), which makes them optically much inferior to diaphane (1.483). Furthermore, Nevillite must be used with absolute alcohol and a clearing agent such as xylene.

MATERIALS AND METHODS

Two simple and efficient techniques were developed permitting the use of diaphane as a mounting medium after staining with Giemsa's, Wright's, Jenner's, and the Eosin Azure II method of Maximow's. In general, the following discussion applies specifically to preparations stained with Giemsa's, since it is used routinely in this laboratory.

The first technique is to be used with alcohol-acetone mixtures, and the second with dioxane as the dehydrating agent. Both give approximately the same results. The advantage of the one method over the other depends on the circumstances in which they are to be used. For ordinary work, or when it is difficult to obtain dioxane, the alcohol method will be most convenient and inexpensive. Since absolute alcohol is not necessary, it will be found especially valuable for work in humid climates, such as the tropics. The dioxane method gives advantages familiar to all who have had occasion to use dioxane.

The staining technique employed was essentially a simplification of Wolbach's¹¹ (1919) method for staining paraffin sections with Giemsa. We have used the technique in staining smears and tissue preparations of bird malaria, Hemoproteus, and fowl pox. Malaria and Hemoproteus parasites stain blue in contrast to the red blood cells which stain a light yellow orange. The general cellular substance takes a rich blue appearance. In fowl pox, the Borrel and Bollinger bodies stain bright red against a blue background. A good account is given in Lee (p. 503) with many helpful suggestions. Hewitt¹² (1939) devised a modification of the Wolbach method which gives fine results for malaria parasites. However, this method is time-consuming and the dehydration and clearing procedure may be much abbreviated when diaphane is used instead of the cedar oil or neutral balsam recommended.

STAINING PROCEDURE

A. *Dry blood smears* were made in the usual manner by running a small drop of blood on the end of one slide along another. The smears were air-dried

and then fixed in absolute methyl alcohol (reagent). They were then allowed to dry and stained with a mixture of 2 drops of the stock Giemsa to each cubic centimeter of water used. After ten to thirty minutes they were removed, washed, and dried. If the slides are to be mounted, diaphane may be applied directly to the dry smear covering with a No. 1 cover slip.

B. *Smears and tissues prepared by dehydration* were always fixed in Maximow's Zenker-formol (10 per cent formalin; no acetic acid). Preparations were immersed in this fluid immediately to avoid drying. Blood or tissue smears were fixed for thirty minutes or less; small pieces of tissue for two to three hours.

(1) *Smears* were washed in water (running preferred) for at least five minutes. If *alcohols* are to be used, pass through to 70 per cent alcohol slightly colored with iodine. Leave for ten to fifteen minutes and remove. Pass smear back through the alcohols to water. Mordant with a 2.5 per cent solution of potassium bichromate for five to ten minutes. Wash and stain with a mixture of 4 drops of stock Giemsa to each cubic centimeter of water used. Usually 2 c.c. of fluid is sufficient to cover a slide completely. Ordinary tap water is satisfactory if slightly alkaline and low in mineral content. Allow blood smears to stain for at least thirty minutes, and tissue smears for as long as two hours. If dioxane is used it is not necessary to include the iodine step at all, since, as Guyer (p. 66) points out, dioxane dissolves bichloride of mercury. With dioxane the smear is passed through at least three changes of pure dioxane and then washed in water and stained as described. The mordant and stain may be conveniently applied by flooding the slides on a staining rack.

(2) *Tissues* dehydrated with *alcohols* were first washed for at least twelve hours in running water. They were then passed through the alcohols in the usual manner, including the iodine step, to absolute alcohol. Clearing and infiltration were done with toluene and absolute alcohol mixtures following the method of Galigher¹³ (1934, p. 122). Imbed and section as usual. Sections should be cut as thin as possible, 4 to 10 microns. The mounted paraffin ribbons were gently heated over an alcohol flame until just melted. The slide was immediately placed into two changes of pure xylene and then passed down through the alcohol series to water. Mordant and stain as for smears. All preparations should be allowed to stain for at least one hour. It is advisable to allow the mordant to remain for at least thirty minutes; longer periods will do no harm. When dioxane is used for dehydration, the tissues are immediately placed in dioxane without any preliminary washing. Change the dioxane at least once and imbed in paraffin, using the procedure of Guyer (p. 65). The mounted sections were heated over an alcohol flame as mentioned above, and then passed through two changes of pure xylene into dioxane. Wash in two changes of dioxane and transfer to water. Mordant and stain as previously described.

MOUNTING PROCEDURE

A. *The Alcohol-Acetone Method.* All Romanowsky-type stains are soluble in alcohol; it is this fact that makes the use of diaphane directly from 95 per cent alcohol impracticable, since a certain amount of the alcohol is carried over to the mounting medium, thus continuing the destaining process. This

eventually ruins the slide in as short a time as a week. In order to obviate this difficulty, the following technique was devised. It applies to both smears and tissues prepared by dehydration.

After staining, the preparations are dehydrated in an alcohol series. Destaining, if necessary, is carried out in 70 per cent alcohol. When a redder color is desired, the tissues may be placed for a few seconds in 95 per cent alcohol to which eosin has been added (1 drop of 0.5 Gm. eosin in 100 c.c. of 95 per cent alcohol to 10 c.c. of alcohol). Transfer from 95 per cent alcohol to solution A. Solution A is a mixture of 30 c.c. of 95 per cent alcohol, 30 c.c. of pure acetone, and 5 c.c. of diaphane. It is readily miscible. Destaining by the 95 per cent alcohol is stopped considerably in this mixture, but the slide should not be left in it longer than a minute. Transfer to solution B. This is a mixture of 55 c.c. of acetone, 10 c.c. of diaphane, and about 1 c.c. of 95 per cent alcohol. When the acetone and diaphane are mixed, a milky white solution results. But as the alcohol is added it clears up completely and remains so indefinitely. The alcohol is conveniently added drop by drop until the desired clear solution is obtained. This small amount of alcohol does not in any way cause destaining. Mount in diaphane.

Slides so prepared and mounted have remained without any evidence of fading for over a year. Preparations may be passed through solutions A and B directly from 70 per cent alcohol without any apparent damage to the tissues. The reason one cannot go straightway from 95 per cent alcohol to acetone to diaphane is that the solubility reaction between these substances is so drastic that the tissues usually crack and are ruined. The adding of diaphane to solutions A and B prevents the tissues from drying out quickly, since acetone is so volatile. It also prevents the acetone from going into solution too rapidly with the diaphane under the cover slip. The use of acetone with Romanowsky stains may be objectionable, but Kingsley¹⁴ (1937) showed that it was not detrimental to such stains.

Diaphane solvent, a preparation of secret formula marketed by some supply houses, may be used with equal success in solutions A and B in place of acetone. If desired, solutions of acetone and the solvent can be employed. Diaphane solvent was miscible in all proportions with 95 per cent alcohol, acetone, and dioxane. When preparations are placed in the undiluted solvent from 95 per cent alcohol, the mixing is rather slow and destaining is not stopped immediately. When the solvent is mixed in excess with 70 or 80 per cent alcohol, a milky white solution, similar to the one described for solution B, results. The addition of a small amount of 95 per cent alcohol clears this up. It is recommended, therefore, that if the diaphane solvent is to be used as the clearing agent, it should be prepared and employed as solutions A and B, substituting it for the acetone.

B. The Dioxane Method. Dioxane was found to be soluble in all proportions with diaphane. As would be expected, it does not destain preparations stained with any Romanowsky-type stains used. This makes it an ideal fluid in which to dehydrate such material for mounting in diaphane (or for that matter in balsam or cedar oil). The following procedure was utilized with much success:

Subsequent to staining, the slides are washed in water and destained, if necessary, in 70 per cent alcohol directly from the water wash. Fifty per cent alcohol works just as efficiently and has the advantage of being less drastic in action. Stop destaining by transferring quickly to pure dioxane. Pass through two changes of dioxane. Mount in diaphane. No clearing agent is necessary. However, if desired, graduated mixtures of diaphane and dioxane may be used to good advantage. Since the dioxane is not so volatile as acetone, it is best to remove some of the excess before mounting, thus allowing the slide to dry more quickly. Preparations mounted in this manner have the advantage over the alcohol-acetone method in that the destaining is stopped abruptly. This results in more uniformly stained tissues.

CONCLUSIONS

1. Diaphane is unconditionally recommended as a mounting medium for preparations stained with any Romanowsky-type stains in place of balsam or cedar oil.
2. An alcohol-acetone and a dioxane method suitable for dehydrating tissues stained with the Romanowsky-type stains are presented. Each method has been used successfully.
3. A simple method for staining tissues with Giemsa which has proved especially useful in bird malaria and fowl pox research is described.

CHEMICAL

SIMPLIFIED PHOTOELECTRIC PROCEDURES FOR MICRO- DETERMINATION OF NONPROTEIN NITROGEN, UREA NITROGEN, CREATINE, AND CREATININE OF BLOOD*

BARNETT SURE, PH.D., AND VIOLET M. WILDER, PH.D.
FAYETTEVILLE, ARK.

SIMPLE and accurate available microchemical methods for the measurement of the nonprotein nitrogen constituents of the blood of the albino rat require more blood than can be obtained from the living animal. The spectrophotometer methods of Borsook¹ could not be introduced, since our laboratory did not possess such an instrument. Furthermore, his procedures were considered too involved for routine use. The recently published electrotitration methods of Borsook and Dubnoff,² while yielding accurate results, were also considered too complex.

With the aid of the Evelyn Macro-Micro Photoelectric Colorimeter,³ a technique was developed for microdeterminations of nonprotein nitrogen, urea nitrogen, creatine, and creatinine. These procedures are so simple and accurate that they can be carried out by any intelligent hospital technician.

NONPROTEIN NITROGEN

Calibration curves were made using the 520 and 440 filters. The Koch and McMeekin⁴ procedure was used for the preparation of the Nessler-Folin reagent for microdeterminations. Instead of working on a 100 ml. basis, the technique adopted was developed on a tenth of a volume basis, i.e., a total dilution to 10 ml., which was carried out in 15 ml. centrifuge tubes graduated in tenths of a milliliter. For the digestion an electrically heated microapparatus, purchased from Eimer and Amend, was used. The Kjeldahl flasks had a total capacity of 10 ml. Tungstic acid blood filtrates were prepared according to the method of Folin,⁵ taking the blood with 7 volumes of ammonia-free water, and precipitating the proteins with 1 part of 10 per cent sodium tungstate made up fresh daily, and 1 part of $\frac{2}{3}$ normal sulfuric acid.

Procedure.—Measure 0.5 ml. of blood filtrate with a 0.5 ml. delivery pipette into a 10 ml. Kjeldahl flask and add 1 ml. of 1:20 sulfuric acid. Digest until fumes appear and add 1 drop of superoxol. Insert a small funnel against the

fume receiver. Heat again until fumes appear, then heat for one minute, timing with a stop watch. Cool and dilute with about 5 ml. of ammonia-free distilled water. Wash out flask with additional distilled water into a 15 ml. graduated centrifuge tube up to 8.5 ml. mark. Then add 1.5 ml. of the Nessler-Folin reagent.⁵ Shake quickly by pouring back and forth from centrifuge tube to absorption tube three times. By such procedure clouding is avoided. Set the blank with reagents at 100 and then read in Evelyn Photoelectric Macro Colorimeter, using the 520 filter, and obtain values from the calibration curve (Fig. 1). The determinations are made in duplicate or triplicate.

The accuracy of the method was tested on two different samples of urine, one on rat's urine and the other on man's urine, using the standard macro-Kjeldahl method for comparison. The results are given in Table I. It is evident from these data that our microprocedure checks to the extent of 1 to 2 per cent with the macro-Kjeldahl method.

TABLE I

URINE	VOLUME (ML.)	NUMBER OF DETERMINATIONS	METHOD	NITROGEN MG. PER ML.	PER CENT ERROR
Rat	0.001	0	Sure and Wilder	58.0	
	1.0	3	Macro-Kjeldahl	58.5	+0.80
	6.0	3	Macro-Kjeldahl	59.0	+1.72
Man	0.02	8	Sure and Wilder	11.52	
	1.0	3	Macro-Kjeldahl	11.76	+2.09

TABLE II

UREA NITROGEN USED FOR ANALYSIS (μ G)	UREA NITROGEN FOUND (μ G)	PER CENT RECOVERY
20.0	20.00	100.00
20.0	20.05	100.25
30.0	31.00	103.30
30.0	32.00	106.60
40.0	41.00	102.50
40.0	30.00	97.50
40.0	39.00	97.50
50.0	52.00	104.00

UREA NITROGEN

To 0.5 ml. of blood filtrate add 2 drops of a phosphate buffer solution⁷ and two drops of a 1 per cent filtered urease solution freshly prepared from Squibb's urease powder. Let stand for one hour at room temperature. Dilute to 7.5 ml. in a 15 ml. centrifuge tube and add 1 ml. of 1:20 sulfuric acid. Transfer from centrifuge tube to absorption tube back and forth twice and shake. This is done to avoid subsequent clouding following addition of the Nessler-Folin reagent. Now add 1.5 ml. of the Nessler-Folin solution. Transfer back and forth to absorption tube three times and shake. Set blank with reagents at 100 and read in photoelectric colorimeter, using the 440 filter, and obtain values from calibration curve (Fig. 1). Recoveries of urea nitrogen by the above micromethod are given in Table II. The nesslerization of the various duplicate or triplicate samples should be done one at a time to prevent clouding.

It is apparent from the results in Table II that our micro urease method yields satisfactory recoveries from known urea solutions. The average error seems to be not greater than ± 3.0 per cent.

CURVES FOR NON-PROTEIN NITROGEN
OF BLOOD
EVELYN MACRO PHOTOELECTRIC COLORIMETER

Fig. 1.

CURVES FOR PREFORMED AND TOTAL CREATININE
OF BLOOD
EVELYN MICRO PHOTOELECTRIC COLORIMETER

Fig. 2.

PREFORMED CREATININE

The Evelyn Micro Photoelectric Colorimeter was used. The ordinary cadmium-coated plungers corroded with saturated picric acid; therefore, gold-plated plungers made by the Rubicon Company of Philadelphia, manufacturers of the Evelyn Colorimeter, were introduced. The 520-M filter was used.

Procedure.—To 1 ml. of blood filtrate add 0.5 ml. of saturated picric acid solution and let stand for ten minutes. Then add 0.1 ml. of 10 per cent carbonate-free sodium hydroxide. After setting the blank with reagents at 100, read the microcolorimeter and obtain values from the calibration curve (Fig. 2).

All attempts to convert creatine to creatinine with either sulfuric or hydrochloric acid, using the micro cells of the Evelyn Photoelectric Micro Colorimeter, yielded irregular results, and such procedure, therefore, had to be abandoned. The following technique was found very satisfactory: To 1 ml. of blood filtrate add 0.5 ml. of saturated picric acid in a 15 ml. centrifuge tube. Cover with lead foil. Autoclave for forty minutes at 20 pounds pressure. Cool. Add 0.1 ml. of 10 per cent carbonate-free sodium hydroxide and allow to stand for ten minutes. Blank with reagents is also autoclaved for the same time at the same pressure. After setting blank at 100, read in the microcolorimeter and obtain values from a separately calibrated curve (Fig. 2). The plungers should be allowed to be in contact with the picric acid not more than a minute or two and then quickly removed from the cell, rinsed with distilled water, and dried. This is done because of the possibility of corrosion by being allowed too much contact with the saturated picric acid solution, particularly since the gold plating is very thin. The difference between the values for the total creatinine and the pre-formed creatinine represents the creatine expressed as creatinine.

Recovery of creatinine from creatine hydrate (Eastman Kodak Co.) is given in Table III.

TABLE III

CREATINE HYDRATE USED (μ g)	NUMBER OF DETERMINATIONS	THEORETICAL AMOUNT OF CREATININE TO BE RECOVERED (μ g)	ACTUAL CREATININE RECOVERED (μ g)	PER CENT ERROR
10.0	6	7.51	7.45	-0.79
5.0	7	3.76	3.85	+2.66

It is evident from the above results that the recovery of creatinine from pure creatine by the simplified technique described is almost complete, the experimental error ranging between -0.79 and +2.66.

Total blood creatinine was determined in 16 rats of different ages from our stock colony, the results ranging from 6.7 to 8.65 mg. per 100 ml. of blood. The average was 7.55 mg. per cent.

SUMMARY

Simplified technique is described for the microdeterminations of nonprotein nitrogen, urea nitrogen, creatine, and creatinine in the blood with the aid of the Evelyn Macro-Micro Photoelectric Colorimeter. This technique can be applied to capillary blood of small laboratory animals as well as human beings.

CLINICAL APPLICATION OF THE MICRODIFFUSION METHOD FOR THE ESTIMATION OF ACETONE*

S. C. WERCH, M.Sc., M.D., CHICAGO, ILL.

IN A RECENT publication¹ regarding the microdiffusion method for the estimation of acetone, the theory and work on which the method is based was discussed. Reference was also made to the clinical application of the method. The purpose of this paper is to offer a rapid procedure which may be used in a clinical laboratory. A comparison is also made between results obtained by this method and by the colorimeter method of Behre and Benedict.²

APPARATUS AND TECHNIQUE

The microdiffusion apparatus is the Conway unit. This unit consists of a small dish of fairly thick glass, resembling a Petri dish (Fig. 1).³ It is divided into two chambers by a circular wall of glass arising from the floor of the dish to about half the height of the outer wall. When in use it is covered with a transparent glass plate and sealed with a fixative.

The Deniges reaction⁴ of acetone precipitation as a basic mercuric compound is utilized. The factors concerned are the time necessary to cause precipitation and the temperature at which the reaction takes place. Two cubic centimeters of Nessler's solution, three cubic centimeters of unknown, and one cubic centimeter of 1 per cent hydrochloric acid are required. Since acetone is volatile, the unknown (urine or oxalated whole blood) should be stoppered as soon as collected and used fresh. The acid is used to fix any ammonia which may be present in the unknown.

Carefully cleaned units are obligatory. This may be accomplished by dipping into cleaning solution and then rinsing consecutively with water, alcohol, and ether.

When ready for use, the units with their covers are placed on a black background, and the edges of the outer wall are smeared with vaseline. Next, the reagents are introduced. First, the central chamber receives the Nessler's solution, and then the acid is run in, distributing it evenly around the outer chamber. The transparent glass plate is next placed to cover the entire unit, except for a small slit, permitting the introduction of the end of the pipette used to carry the unknown—urine or oxalated whole blood. A stop watch held in one hand is

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.

Received for publication, February 10, 1940.

Fig. 1.

NOMOGRAPHIC CHART

started as soon as the pipette containing the unknown, held by the other hand, stops flowing freely. The hand holding the watch next slides the glass plate so that it completely covers the unit, as an immediate gesture after starting the watch. When the endpoint is reached the watch is stopped. Rapid introduction of the unknown is best done with a pipette possessing a large opening. The endpoint is the appearance of precipitation of the Nessler's solution at the periphery of the inner chamber of the unit in the form of threads, like spokes of a wheel, or as a cloud. It is that second when the spokes or cloud extend inward 1 mm.

The temperature factor may be controlled without great loss of accuracy by placing the reagents and utensils in a cool (20° C.) corner of the laboratory for an hour. The reading on a thermometer hung close by may be used. Time readings varying no more than ± 2 seconds from three tests may be averaged and considered sufficient. The temperature and time factors thus obtained are then located on the nomogram (Fig. 2) with a straight edge, and the concentration of acetone is read off in the center.

COMPARISON WITH BEHRE-BENEDICT METHOD

It was considered well to compare this method with another of proved value.

The following dilutions of specified acetone in human urine and oxalated ox blood were made from a 1 per cent solution and estimated by the two methods: 1:500, 1:1,000, 1:3,000, 1:7,000, and 1:10,000. Incubation of the apparatus and reagents was again resorted to in our method in order to control better the temperature factor. Table I shows the values obtained.

TABLE I
ACETONE IN MILLIGRAMS PER 100 C.C. OF URINE OR BLOOD

DILUTIONS	ACETONE IN HUMAN URINE		ACETONE IN OXALATED WHOLE OX BLOOD	
	MICRODIFFUSION METHOD	BEHRE-BENEDICT METHOD	MICRODIFFUSION METHOD	BEHRE-BENEDICT METHOD
1:100	95.00	98.00	90.00	95.00
1:500	19.50	19.50	19.00	19.50
1:1,000	10.00	9.50	11.00	9.50
1:3,000	3.50	3.00	3.00	3.50
1:7,000	1.50	2.00	1.50	2.50
1:10,000	1.20	1.50	1.30	1.80

SUMMARY

The microdiffusion method for the estimation of acetone has been modified to fit the needs of the clinical laboratory. With a little practice a urine or blood sample may be determined in five to ten minutes.

This work was begun at Trinity College, Dublin, under the direction of Professor W. R. Fearon, of the Department of Biochemistry. I wish to thank him for his interest and kind assistance. I also wish to thank Mr. Einhart Kameran, who took part in the development of the technique.

A CLINICAL METHOD FOR EXTRACTION OF URINARY ANDROGENS PRELIMINARY TO COLORIMETRIC QUANTITATION BY OESTING'S TECHNIQUE*

W. KENNETH CUYLER,† M.A., AND MARGARET BAPTIST
DURHAM, N. C.

ALL those engaged in the quantitation of urinary androgens have felt the need of a method less expensive and requiring a shorter period of time for completion than those of bio-assays which employ capons or baby chicks. It was with enthusiasm, therefore, that clinicians and research workers turned to the reports of Zimmermann for a chemical method for the determination of urinary androgens.

Zimmermann demonstrated^{1, 2} that the steroid sex hormones could be determined quantitatively by the use of meta-dinitrobenzene by means of a characteristic color reaction which occurred in the presence of an alkali with compounds containing an active methylene group. Since his work was done chiefly with crystalline sex steroids, an application of the "Zimmermann reaction" had to be devised for urinary extracts.

Several such methods had been described as suitable for the determination of urinary androgens when the procedure described herein was initiated.³⁻⁵ Careful consideration was given to these methods, with particular regard to the expense of new equipment necessary, the relative simplicity of the technique, the time elements involved, and the practicality of doing consecutive daily assays on a number of patients. Oesting's method⁴ seemed to satisfy best our requirements.

The method for extraction used by Oesting is essentially that of Gallagher and Koch.⁶ In their procedure benzol was the solvent employed and the extraction was carried out in a continuous extractor. We have modified the method of extraction so as to eliminate the use of benzol and the continuous extractor. Although the latter is very efficient, it is of such dimensions as to be impracticable in the smaller clinical laboratories. Because of its high toxicity and inflammability, benzol is a dangerous solvent to use in the average laboratory space.

The extracting medium employed in the procedure described below is dibutyl ether.⁷ Besides being a thoroughly satisfactory solvent⁸ for steroids, dibutyl ether has a number of advantages over other solvents. It is practically nontoxic and is nonirritating to the mucosa of the air passages. It has a low kindling

†Ciba Fellow in Clinical Endocrinology.

¹Secured from the Union Carbide and Carbon Corporation, Long Island City, New York.

point, and, a fact which is very important, urinary pigments are only slightly soluble in it. The extractions can be made in a simple apparatus. The recovery after distillation is approximately 90 per cent, and the solvent can be used a second time before redistillation is necessary.

METHOD OF EXTRACTION

An aliquot fraction of a twenty-four-hour specimen of urine (not less than 200 c.c., if possible) is acidified, using 5 c.c. of concentrated sulfuric acid (reagent) per 100 c.c. of urine. Hydrolysis is accomplished by autoclaving for fifteen minutes at 15 pounds pressure. When cool the urine is extracted three times with dibutyl ether. Fresh solvent is used for each extraction. For specimens which are more than 500 c.c. in volume, 20 c.c. of solvent per 100 c.c. are used; for specimens of less than 500 c.c. in volume, only two extractions are made, using 150 c.c. of solvent for each extraction. The extraction is carried out in thin-walled, globe-shaped 2L separatory funnels by violent shaking by hand at the rate of 180 shakes per minute for three minutes for each extraction.

The combined dibutyl ether extracts are washed with (1) 100 c.c. of 10 per cent sodium hydroxide, (2) 100 c.c. of sodium bicarbonate solution saturated at room temperature, and (3) 100 c.c. of tap water. These amounts are used when the amount of dibutyl ether extract is 300 c.c. or less. Proportionately more of the solutions must be used if the volume of dibutyl ether extract is greater than 300 c.c. (By washing the dibutyl ether extract with the two alkalis, the estrogens are partially removed. These are completely removed in a subsequent step. The strong alkali breaks down the emulsion which sometimes had formed and removes most of the pigment which had been extracted by the solvent.)

The washed dibutyl ether extract is then transferred to a 2L distillation flask, and the solvent is removed by steam distillation under reduced pressure. When dry the flask is washed out three times with ethyl ether, using a total of 100 c.c. (Anesthetic ether is used in order to employ a product as nearly peroxide and aldehyde free as possible.)

The ethyl ether extract of the dry residue is transferred to a 125 c.c. separatory funnel where it is washed with 20 c.c. portions of 10 per cent sodium hydroxide until the washings are clear. This usually requires three to five washings, occasionally more. The ethyl ether extract is then washed three times with 20 c.c. of distilled water.

The ethyl ether extract is transferred to a 250 c.c. beaker containing approximately 0.5 Gm. of decolorizing charcoal.* The solution is thoroughly stirred, and the charcoal is allowed to settle out before filtering. The charcoal is well washed with additional ether. To complete the final step in the extraction of the urinary androgens, the ether is allowed to evaporate or it is evaporated to dryness over a steam bath.

Occasionally faulty filter paper will allow the passage of some charcoal. This cannot be observed until the ether is all evaporated. In this event the extract should be taken up in 100 c.c. of ether and refiltered. Although discoloration due to charcoal is obvious, there occasionally appears a brownish residue in the beaker after evaporation of the ether, for

*"Norit-A," purchased from the Arthur H. Thomas Co., Philadelphia, Pa.

which no explanation is offered. This brown residue is difficult to remove by further treatment with charcoal. Moreover, additional treatment with charcoal and subsequent filtering so greatly reduces the steroid content of the ether extract that subsequent colorimetric determinations are valueless.

New lots of charcoal should be checked against the charcoal being used with regard to steroid adsorption and general quality of the powder. One brand of charcoal allowed no measurable amount of steroids to pass through the filter. Other brands have given trouble with regard to colored or muddy-appearing residues after evaporation of the ether extract.

COLORIMETRIC DETERMINATION

No changes have been made in the colorimetric determination part of Oesting's procedure. The colorimeter used is one designed by Oesting with the assistance of the Hellige Manufacturing Co.

It has been our constant practice that one of us (W.K.C.) attend to the extraction of specimens and the other (M.B.) carry out the colorimetric procedure. We believe that in this manner personal error has been minimized.

The following data, representing 220 colorimeter readings, illustrate the accuracy which is obtained by careful technique:

110 determinations made in duplicate
68 of these, or 62 per cent, matched
42 of these, or 38 per cent, did not match

Of the 42 which did not match
15 differed by only 0.1 color unit
9 differed by only 0.2 color unit
7 differed by only 0.3 color unit
8 differed by only 0.4 color unit
2 differed by only 0.5 color unit
1 differed by only 0.7 color unit

Although this method does not permit qualitative identification of any member of the androgen group, it is felt that these data on total "androgens" as a group (17-ketosteroids) are of very definite value. This value is enhanced by consecutive daily determinations. It has been shown by our group that there is a marked variation in the daily excretion of these compounds by women.⁹ These variations take on some significance in view of the apparent accuracy of the method.

SUMMARY

A clinical method for extraction of urinary androgens, preliminary to colorimetric quantitation, has been described. Dibutyl ether is substituted for benzol as the solvent. The advantages of dibutyl ether are enumerated.

The method of extraction is adaptable to the average laboratory and is practicable for assaying consecutive daily specimens on a number of patients concurrently.

We wish to express our indebtedness and thanks to Dr. E. C. Hamblen, Chief of Endocrine Division, for his constant support and helpful criticism.

SYRINGE TYPE GLASS ELECTRODE FOR THE MEASUREMENT OF BLOOD PH*

OTTO H. MÜLLER, SC.D., AND E. COOPER PERSON, JR., M.D.
NEW YORK, N. Y.

MANY glass electrodes have been designed for measuring the pH of blood as it exists in the body, but there are relatively few that are free from objections. To be satisfactory for blood analysis, the electrode not only must conform to the usual standards for glass electrodes but also must meet the following additional requirements:

- (1) Analysis of small samples of blood should be possible.
- (2) The blood must not be altered by coming into contact with air or by getting mixed with another solution.
- (3) The blood should not undergo marked changes in temperature.
- (4) The pH of the blood must be measured quickly, before glycolysis sets in.
- (5) The blood should be obtained without stasis and without the use of suction by means of a syringe.

In our opinion, the electrode described here† meets all these requirements and has additional features which make it suitable for other studies. We have used it for over a year with very satisfactory results.

The drawing in Fig. 1 shows the construction of the electrode. It is a modification of the type developed by MacInnes and Belcher¹ in which the glass membrane is well protected because it forms the inner tube of the electrode. The tip at A is ground to fit a standard Luer hypodermic needle. The ground surface at B makes it possible to seal the electrode with a glass stopper, or to

†Obtainable from Mr. Otto Hopf, Flushing, N. Y.

introduce the tip of a standard syringe so that the electrode forms an extension of the barrel of the syringe. The over-all length of the electrode is 9 cm., and only 0.5 c.c. of blood is necessary to fill it completely. At *C* a reference solution and electrode are introduced; we have used 0.1 N hydrochloric acid and a silver-silver chloride electrode,² sealed into place with De Khotinsky cement. The electrode is rugged and convenient to handle; furthermore, the straight glass membrane can be easily cleaned by means of a soft feather and water.

Fig. 1.—Syringe type glass electrode and special plug for measurement of oxidation-reduction potentials.

The measurements were made with a Beckman pH meter which permitted readings accurate to 0.03 pH units. To insure constant temperature the glass electrode and calomel half cell are hung in a saturated solution of potassium chloride which is kept at the desired temperature by circulating water. A sketch of the small water bath which was constructed to fit the Beckman pH meter is shown in Fig. 2. A simple brass clip attached to a bakelite block (Fig. 2) insulates the glass electrode from the pH meter and holds it in place. The potassium chloride solution serves further as a liquid junction between the glass electrode and the calomel half cell.

Often it is desirable to measure oxidation-reduction potentials as well as the pH of the same solution. If instead of the glass stopper, a special plug (Fig. 1, *D*) is used into which a platinum wire has been sealed, both measurements can be carried out on the same sample and with the same meter.

Operation of the Electrode.—The electrode is warmed to the desired temperature and calibrated with several buffers of known pH. It is advisable to use buffers with pH values near that of the unknown. When repeated meas-

urements prove the satisfactory performance of the electrode, it is washed in the warm circulating water and rinsed with a warm solution of heparin in physiologic saline solution. A sterile hypodermic needle is then attached to tip A and the blood vessel is punctured. During the sampling the electrode temperature is kept near body temperature by holding it covered with the hand. If arterial blood is taken, the electrode will fill very quickly because little resistance is offered by the straight barrel of the electrode to the flow of blood.

Fig. 2.—Sketch showing glass electrode, calomel half cell, and water bath attached to door of pH meter. Raising the water bath will immerse the electrodes in a saturated solution of potassium chloride which serves as liquid junction.

If venous blood is taken, the electrode has to be held in a horizontal position, or slight stasis of the vein becomes necessary to force the blood through the electrode. In addition to the 0.5 c.c. which is necessary to fill the electrode, another 0.5 c.c. of blood is passed through the electrode. This washes out any excess heparin so that the composition of the blood should be the same as that in the blood vessel. While the blood is still flowing, the electrode is stoppered. It is then withdrawn and hung into the potassium chloride solution after the needle has been removed. Stable potentials are obtained immediately. The whole procedure requires less than one minute.

The pH values obtained are reproducible if the blood samples are taken from the same person within an hour. In agreement with the observations of others,^{3, 4} we found that the presence of heparin does not have a measurable effect on the pH; neither does clotting alter the observed pH⁵. However, if the blood is left in the electrode more than five minutes, a drift to a lower pH, due to glycolysis, is noticeable.^{4, 5} Some studies made with this electrode on the blood pH of normal and hypertensive dogs are published elsewhere.⁶

COMPARATIVE STUDY ON A NEW SIMPLE METHOD OF SULFANILAMIDE DETERMINATION IN BLOOD*

MASON C. ANDREWS, B.A., AND ARNOLD F. STRAUSS, M.D.
NORFOLK, VA.

THE extensive use of sulfanilamide treatment and the recognized importance of attaining and maintaining an optimal blood concentration make it very desirable to have a method which combines simplicity and accuracy in estimating this blood concentration.

In this country the method developed by Marshall (1937) is accepted as satisfactory. Recently, Werner (1939) described in *Lancet* a novel method for which he claims advantages over Marshall's diazotization reaction; namely, simplicity of technique, which results in a considerable saving of time, and the use of only reliable reagents, since the new method eliminates the use of the unstable coupling agent, dimethylnaphthylamine. This method is based on the direct formation of a yellow color when Ehrlich's reagent, para-dimethylamino-benzaldehyde, is added to the filtrate from blood containing sulfanilamide.

There has been no report of investigation of this method in American literature. The purpose of this publication is to compare Werner's method with that of Marshall.

About fifty determinations of free sulfanilamide in blood in varying cases have been made by this method. The following procedure incorporating some modifications was found satisfactory: 2 c.c. of oxalated blood are added drop by drop from a pipette to 8 c.c. of a 5 per cent solution of trichloroacetic acid. The blood protein is thereby immediately precipitated and is easily filtered off, yielding a clear filtrate. Next 3 c.c. of fourth-normal sodium hydroxide is added to 4 c.c. of filtrate, followed by 1 c.c. of Ehrlich's reagent. The yellow color develops immediately to its maximal intensity. It is compared in the colorimeter to the color developed by adding 1 c.c. of the reagent to 7 c.c. of a standard solution of sulfanilamide in distilled water, or by diluting 1.25 c.c. of the reagent to 10 c.c. with the standard. The standard, containing 0.08 mg. of sulfanilamide

*From the Pathological Laboratory of St. Vincent's Hospital, Norfolk.
Received for publication, February 24, 1940.

per 7 c.c. of water, is conveniently prepared by dissolving 0.8 Gm. of sulfanilamide in 700 c.c. of water, or 1.143 Gm. of sulfanilamide in 1,000 c.c. of water and diluting 1:100.

If the unknown is set at 10 in the colorimeter, the readings of the standard will be milligrams per hundred cubic centimeter of blood. When the concentration of the unknown exceeded 10 mg., exact results were not obtained. However, if the unknown is set at 5 and the readings of the standard are multiplied by 2, the results are exactly accurate.

The reagents used include: 5 per cent trichloroacetic acid, Ehrlich's reagent (3 Gm. of para-dimethylaminobenzaldehyde added to 100 c.c. water containing 3 c.c. of concentrated sulfuric acid), and fourth-normal sodium hydroxide.

TABLE I

MG. SULFANILAMIDE IN 100 C.C. BLOOD	AVERAGE RESULTS BY METHOD OF:	
	WERNER	MARSHALL
2.5	3.1	2.5
5.0	5.1	5.0
7.2	7.0	6.8
9.0	8.9	8.9
10.3	10.6	10.1
13.0	13.0	12.9
15.0	14.9	14.8

Table I shows the results obtained by Marshall's method compared with those obtained by Werner's method. Examination of blood to which sulfanilamide has been added to produce known concentrations showed essentially identical results.

Examination of the blood of sulfanilamide-treated patients likewise yielded the same results by both methods. There has not been any interference by other medications given to the patient.

Werner's method is accomplished by an extremely simple procedure which seems to make it superior for large scale use and saves considerable time for a single determination. The time required for one test by Marshall's method was about fifty minutes, although only fifteen minutes of that time was spent in actual manipulation. A determination by Werner's method can be completed in twelve minutes. The stability of the color developed by this procedure makes possible the use of a single standard solution for a large number of determinations. It fails to show appreciable change after two weeks' time. Ample time is available for reading the tests, and a number may be done simultaneously and read when convenient. The color formed by Marshall's procedure deteriorates rapidly, and each test must be read at a definite time, eliminating the possibility of carrying out many tests entirely simultaneously. A new standard must be made at least for each series of determinations.

Although the dimethylaminobenzaldehyde solution has a slight yellowish color, the distortion caused by it is not significant, except at very low concentrations (Table I). If the dimethylaminobenzaldehyde crystals are very old and show a greenish-brown color, the resulting solution is too yellow for use.

Werner's method is equally satisfactory for sulfapyridine determination. A sulfapyridine standard may be made or the sulfanilamide standard used and the result multiplied by 1.5 to correct for differences in molecular weight.

Werner also describes a very simple procedure for the determination of sulfanilamide in urine. He further gives directions for making a permanent set of standards from potassium chromate for use in a color comparator. Their use did not prove to be very satisfactory.

A disadvantage of Werner's method is that the yellow color developed is more difficult to compare in the colorimeter than the reddish one obtained by Marshall's procedure.

SUMMARY

A new method for determination of sulfanilamide in blood developed by Werner has been compared with that of Marshall. This method gives accurate results while allowing a considerable saving of time. The reagents used, as well as the standard solution, are stable.

The disadvantage of this method is its use of yellow for colorimetry.

RAPID VOLUMETRIC DETERMINATION OF URINARY SODIUM*

EVAN W. MCCHESNEY, PH.D., RENSSELAER, N. Y.

RECENTLY Strauss¹ demonstrated that urine, to which has been added thorium nitrate and sulfuric acid, can be ashed very rapidly in silica beakers in an electric muffle furnace. The method was developed primarily for the determination of potassium and, although the author suggested that it might be adapted to the determination of sodium, she did not establish the fact that this could be done. Her method is much more convenient than the older one of Stolte² as applied by Tisdall and Kramer³ which is both tedious and time-consuming.

We wished, in this laboratory, to make a large number of sodium determinations and none of the methods now available seemed suited to our needs because of the time they required. We, therefore, decided to try to combine the rapid ashing technique of Strauss with the determination of sodium as the pyroantimonate by the method of Kramer and Gittleman,⁴ and we found that such a combination was very satisfactory. With these combined techniques one may determine sodium in duplicate on as many as eight urine samples in about five hours of elapsed time, or about three hours of actual work.

*From the Research Laboratories, Winthrop Chemical Co.
 Received for publication, April 15, 1940.

Reagents.—All solutions are prepared as described in the original articles with one exception: the solution used to extract the ash must be 0.4 per cent phosphoric acid instead of the 0.1 per cent solution recommended by Strauss. The reasons for this will be set forth below. This reagent, 10 per cent thorium nitrate, 10 per cent potassium hydroxide, and potassium pyroantimonate reagent are kept in paraffin-lined bottles.

Procedure.—An amount of urine containing 15 to 25 mg. of sodium (ordinarily this would be 5 to 7 c.c.) is measured into a silica beaker of 50 or 100 c.c. capacity, together with 1 c.c. of 10 per cent thorium nitrate and 1 c.c. of 4 N sulfuric acid. The material is evaporated on the water bath, ashed and extracted (with 0.4 per cent phosphoric acid), as described by Strauss. Samples of 1 c.c. of the extract are taken for analysis. To these samples are added 4 drops of 10 per cent potassium hydroxide to neutralize the phosphoric acid, after which the procedure followed is that of Kramer and Gittleman as modified by Eisenman.⁵

Fig. 1.—Relationship of concentration of sodium to the amount found.

Interference of Thorium.—In her article Strauss states that the ashes extracted with 0.1 per cent phosphoric acid are thorium free, but this has not been our experience. Such extracts contain considerable amounts of thorium, which is precipitated by the pyroantimonate reagent, and therefore give high results. Data bearing on this point are given in Table I.

TABLE I
INTERFERENCE OF THORIUM WITH SODIUM DETERMINATION

SAMPLE NUMBER	H ₂ PO ₄ USED FOR EXTRACTION (%)	SODIUM TAKEN* (MG.)	SODIUM FOUND (MG.)	BLANK VALUE
1	0.1	3.14	3.83	0.69
2	0.1	2.61	3.31	0.70
3	0.1	0.00	0.70	0.70
4	0.4	3.14	3.27	0.13
5	0.4	0.00	0.17	0.17

*Per cubic centimeter of ash solution.

Limits of the Method.—The work of Kramer and Gittleman indicated their method to be accurate within ± 2 per cent. Balint⁶ has claimed that the method gives results which are about 3 per cent higher than the theoretical, and Peters and Van Slyke⁷ suggest that the results be divided by a factor of 1.03. It should be noted that Eisenman, and Peters and Van Slyke, give the impression that the method is accurate only when the amount of sodium determined

is between 2 and 3.75 mg. per cubic centimeter of ash solution. Balint, on the other hand, gives the permissible range as 0.5 to 6 mg. We felt that this point was worthy of further study and have found that the range of 1.0 to 7.5 mg. gives a reasonable degree of accuracy (Fig. 1).

TABLE II
ANALYSIS OF URINE WITH ADDED SODIUM CHLORIDE

SAMPLE NUMBER	COMPOSITION OF SAMPLE (C.G.)		SODIUM FOUND TOTAL (MG.)	SODIUM ADDED (MG.)	SODIUM RECOVERED (MG.)	PER CENT RECOVERY
	URINE	0.8% NaCl				
1	5	0	18.80	0		
2	5	1	21.97	3.14	3.17	100.9
3	4	2	21.39	6.29	6.35	100.9
4	3	3	20.82	9.43	9.54	101.2
5	2	4	20.14	12.58	12.62	100.3
6	1	5	18.51	15.72	14.75	93.8*

*The results have invariably been low when 1 c.c. samples of urine (and, occasionally, 2 c.c. samples) were ashed, probably because of the bulky and gelatinous precipitates formed in the ash solutions. Apparently in these cases a smaller proportion of the thorium is converted to the oxide, hence more is left to form the phosphate. A similar situation was encountered in analyzing the synthetic urines described in Table III; this probably explains the low results obtained on these samples.

TABLE III
ANALYSIS OF MIXTURES OF KNOWN COMPOSITION

SUBSTANCE	SAMPLE A	SAMPLE B	SAMPLE C
NaCl	20 Gm.	10 Gm.	None
Other salts*	10.25 Gm.	10.25 Gm.	10.25 Gm.
Urea	20 Gm.	20 Gm.	20 Gm.
Water added	1,200 c.c.	1,200 c.c.	1,200 c.c.
Mg. sodium per c.c., theory	0.55	3.27	0.0
Mg. sodium per c.c., found	6.31	3.20	0.0

*The composition of this mixture was 6 Gm. of KH_2PO_4 , 1.1 Gm. of $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.65 Gm. of MgSO_4 , and 2.5 Gm. of $(\text{NH}_4)_2\text{SO}_4$.

Accuracy of the Method as Applied to Urine.—This accuracy has been demonstrated in three ways: (1) recovery of sodium added to urine (Table II), (2) analysis of known mixtures approximating the composition of urine (Table III), and (3) demonstration of the agreement of the values obtained with those of the gravimetric method of Butler and Tuthill.⁸ It might be stated further that the method is remarkably precise, since it is not at all unusual to have all the pairs of five duplicate determinations agree within 0.02 mg. sodium (that is, about 0.7 per cent difference), and differences of as much as 0.05 mg. are very rare.

THE STANDARDIZATION OF pH MEASUREMENTS WITH A PRECISION GLASS ELECTRODE AT VARIOUS TEMPERATURES*

ALBERT GLAUBIGER, M.S., NEW YORK, N. Y.

INTRODUCTION

THE pH values of a number of biological products and bacterial media, obtained by colorimetric and electrometric methods, have been presented in some recent papers.^{1, 2} In several procedures employed, the test fluids were diluted with fixed quantities of distilled water or physiologic saline solution. In the present work the pH values of a number of buffer mixtures, diluted with varying quantities of distilled water and saline solution, have been determined between the temperatures of 10° C. and 38° C. Since the measurement of pH values is so fundamental in all biological laboratories, the use of a standard pH scale is essential. The pH scale adopted throughout this work is based upon the pH values of primary potassium phthalate. The pH values of the buffer mixtures studied here have been tested by employing these values in computing the dissociation constants of the corresponding buffer acids by means of an approximation of the Debye-Hückel limiting law.

Earlier work on the standardization of the pH scale has been fully described by Clark.³ Recent studies of Hitchcock,^{4, 5} MacInnes,⁶ and their associates have provided a fundamental basis for further pH studies. Our work is based essentially upon the methods employed by these workers.

The dissociation constant K' of a weak acid HA is a function of the pH value of a solution of the acid and its salt:

$$pK' = pH - \log \frac{C_A}{C_{HA}} \quad (1)$$

By replacing the stoichiometric concentrations C_A and C_{HA} by the activities of the acid and its negative ion constituent, pK' may be expressed as a function of the thermodynamic dissociation constant K :

$$pK' = pK + \log \frac{f_A}{f_{HA}} \quad (2)$$

For moderately dilute solutions Hitchcock has proposed an approximation of the limiting law:⁷

$$\log \frac{f_A}{f_{HA}} = B\mu - A \sqrt{\mu} \quad (3)$$

where A is the familiar Debye-Hückel constant and B is a constant independent of the concentration but may vary for different solutes. The preceding expres-

*From the William Hallock Park Laboratory, Bureau of Laboratories, Department of Health, New York.

Received for publication, March 13, 1940.

sion for $\log \frac{f_A}{f_{HA}}$ is substituted into equation (2); pK' is obtained as a function of the thermodynamic dissociation constant and of an approximate form of the limiting law:

$$pK' = pK - A \sqrt{\mu} + B\mu \quad (4)$$

The following procedure was employed in our work. pK' values were first computed from the measured pH values of the buffer mixtures by means of equation (1). It was found that by employing the apparent linear relation between the expression $(pK' + A \sqrt{\mu})$ and the ionic strength μ , the constants pK and B in equation (4) could then be evaluated by the Method of Least Squares. pK' values for the buffer acids computed by means of equation (1) were then compared with pK' values computed by means of equation (4). The deviations between the two sets of pK' values for a given buffer acid at a given temperature serve as a measure of the degree of conformity of the pH scale adopted in this work with thermodynamic principles and an approximate form of the Debye-Hückel theory.

The foregoing method was essentially that of extrapolation employed by Bjerrum and Unmack⁸ to evaluate the thermodynamic dissociation constant of citric acid and other weak acids at various temperatures.

EXPERIMENTAL

The procedure adopted consisted in the measurement of pH values of buffer solutions set up in a galvanic cell with liquid junction:

Glass, Solution X:KCl (saturated): HgCl, Hg

An Electron Ray Meter was employed in conjunction with a MacInnes-Belcher durable condenser type glass electrode. The latter has been amply described in the literature.⁹⁻¹¹ The Electron Ray Meter is a potentiometer capable of recording either millivolts or pH units. The essential parts of the meter consist of a cathode-ray tube which in conjunction with a triple grid pentode detector and amplifier, operate as null-point indicator. In these determinations the instrument was set to record directly in pH units.

Buffer solutions were prepared with Baker's "analyzed" salts. A 0.05 molar solution of primary potassium phthalate ($KHC_8H_4O_4$) was employed as a primary pH standard. The latter was prepared from the crystalline salt purchased from the National Bureau of Standards. The pH values of this solution have been carefully determined by MacInnes and his associates.⁶ Using their work as a basis, the following pH values of 0.05 molar $KHC_8H_4O_4$ were adopted as standards of reference throughout this work:

t°C.	pH
10	4.00
25	4.00
38	4.02

Test solutions were prepared from the buffer mixtures by dilution with appropriate volumes of distilled water or 0.1454 molar sodium chloride solution.

pH measurements were carried out by enclosing the glass electrode filled with the test fluid in an electrically grounded metal case, which in turn was

enclosed in an incubator with thermostatic temperature control. By means of the latter the temperature around the glass electrode assembly (glass and calomel electrodes) was kept constant within $\pm 0.5^\circ \text{C}$. during any measurement. When not in use, the glass electrode was filled with distilled water. By this practice the residual potential within the glass membrane (asymmetry potential) is maintained at a low constant level.¹⁰

EXPERIMENTAL RESULTS

The pH values of the unknown test solutions in the accompanying tables represent the results of at least three concordant measurements at each temperature. For the test solutions between pH 4.0 and 9.0, the MacInnes-Belcher glass electrode in conjunction with the Electron Ray Meter, functioned accurately, well within the limits ± 0.02 pH unit. For test solutions having values ranging from pH 9.0 to 9.3, the accuracy of the instrument was reduced to about ± 0.03 pH unit. Employing the pH values assigned to the standard phthalate buffer, the apparatus yielded pH values for the undiluted buffers which differed from the values obtained by Hitchcock and MacInnes with the hydrogen electrode by ± 0.01 pH unit. However, the pH values of the acetate buffer mixture at 25°C . and that of the borate buffer at 38°C . differed from the values obtained by MacInnes and Hitchcock by ± 0.02 pH unit.⁴⁻⁶

The following values of the Debye-Hückel constant A^{12} were employed in equation (4):

$t^\circ \text{C}$.	A
10	0.493
25	0.506
38	0.519

The value of A at 10°C . was obtained by graphical interpolation. Between 0°C . and 18°C ., A is approximately a linear function of the temperature.

Table I summarizes the results obtained with the phosphate buffer mixtures at 25° and 38°C . Since these solutions consist of 1:1 buffer mixtures, C_A and C_{NA} are equal and the pK' values computed from equation (1) are numerically equal to the measured pH values of the buffers. Likewise pK'' values are equal to the measured pH values of the saline buffer mixtures. The pH values have, therefore, been omitted from this table.

Column (1) gives the dilution factor or the percentage dilution with distilled water or 0.1454 molar sodium chloride solution. Columns (2) and (3) give the molar concentrations of primary potassium phosphate (KH_2PO_4) and secondary sodium phosphate (Na_2HPO_4), respectively. Column (4) gives the values of the ionic strength of the test solutions. Column (5) gives the observed and calculated pK' values of the buffer acids by means of equation (1) and equation (4), respectively. Columns (6), (7), and (8) contain data for the buffer solutions diluted with 0.1454 molar sodium chloride solution, which have been included in the table for comparison with the corresponding data in aqueous solution (Table I).

For the phosphate buffer mixtures equation (4) was altered in accordance with the interionic attraction theory by the use of $3A$ in place of A . The ionic strength of the aqueous buffer solutions was taken as four times the con-

*To compute pK' from equation (4):

$$10^{\circ} \text{ C. } pK' = 4.76 - 0.493 \sqrt{\mu} + 0.61\mu.$$

$$25^{\circ} \text{ C. } pK' = 4.78 - 0.506 \sqrt{\mu} + 0.87\mu.$$

$$38^{\circ} \text{ C. } pK' = 4.76 - 0.519 \sqrt{\mu} + 0.52\mu.$$

centration of either phosphate salt. The ionic strength of the saline buffer solutions was taken as the molar concentration of sodium chloride and four times the molar concentration of either phosphate salt. The average differences between pK' values obtained from equation (1) and those computed from equation (4) are ± 0.01 and ± 0.00 at 25°C . and 38°C ., respectively.

Fig. 1.—Extrapolation of pK' data for acetate buffers, triangles; phosphate buffers, circles; and borax buffers, squares.

The data for the borax buffers are summarized in Table II. The following possible paths of the hydrolytic reactions have been proposed:⁴

Hitchcock has shown that neither reaction (A) nor reaction (B) go to completion, as indicated by an actual alkalinity of 2×10^{-5} mols per liter of hydroxyl ions in the borax solutions. He suggests that this may be due to a reaction between the borate ion and water to form undissociated acid. Therefore, C_{HA} was obtained by adding C_{OH} (2×10^{-5} mols per liter) to the molar concentration of sodium borate. Likewise, C_A was taken as equal to the difference between the molar concentration of borax and the hydroxyl-ion concentration.

Since pK' values computed by means of equation (1) were numerically equal to the observed pH values, the latter have been omitted from the table (Table II).

For the aqueous borax solutions the ionic strength was taken as twice the molar concentration of sodium borate. For the borax buffers diluted with sodium chloride solution, the ionic strength was taken as the sum of the molar concentration of sodium chloride and twice the molar concentration of sodium borate. The average differences between pK' values obtained from equation (1) and those computed by means of equation (4) are ± 0.00 , ± 0.00 , and -0.01 at 10°C ., and 25°C ., and 38°C ., respectively.

Table III summarizes the data for the acetate buffer mixtures. Both the ionic strength of the aqueous buffer mixtures and the concentration of the negative ion constituent, C_A , were taken as equal to the molar concentration of sodium acetate. The concentration of the undissociated acid, C_{HA} , was taken as equal to the molar concentration of acetic acid in the buffer mixtures. The ionic strength of the saline buffers was taken as the sum of the molar concentrations of sodium chloride and sodium acetate.

The average differences between pK' values obtained from equation (1) and those computed by means of equation (4) were $+0.01$ at 10°C ., 25°C ., and 38°C ., respectively, for the acetate buffers.

Fig. 1 shows graphically the method of extrapolation employed to evaluate the constants pK and B in equation (4). The points on the lines were obtained by the Method of Least Squares, using the appropriate data in Tables I, II, and III for aqueous solutions of the phosphate, borate, and acetate buffer mixtures. The best straight lines were then drawn through these points (Fig. 1). The intercepts on the $pK' + A\sqrt{\mu}$ axis give the pK values of the buffer acids at infinite dilution. A comparison of limiting pK values obtained in this study with those obtained by others is given in Table IV.

DISCUSSION

Examination of the pH data in the tables shows that the pH values of all the buffer solutions increase with increasing aqueous dilution. While the increases are relatively small for the acetate and borate buffer mixtures, the phosphate buffer suffered a large increase in pH, amounting to 0.2 pH unit at 90 per cent dilution with distilled water. On the other hand, all the buffer mixtures suffered a marked decrease in pH, with increasing dilution with sodium chloride solution. These results are in agreement with those obtained by other workers.^{8, 17} Moreover, while increases in temperature affected the undiluted acetate and phosphate buffers least, the borax buffer suffered a decrease of 0.25 pH unit between 10° and 38° C. It has already been pointed out that the pH values of the undiluted buffers showed good agreement with the values obtained by Hitehoeek and MacInnes with the hydrogen electrode.

Since it is possible to measure mean ionic activities only, pH as a function of the negative logarithm of the hydrogen-ion activity cannot be placed on a strict theoretical basis. With this fact in mind, any attempt to provide a strict thermodynamic basis for the pH scale is necessarily limited. The efforts of MacInnes and his associates in this direction are noteworthy. Employing extremely dilute buffers, they applied the limiting law to pK data on acetate buffer mixtures at 12° C., 25° C., and 38° C. However, values of the Debye-Hückel constant A were obtained which were greater than those required by theory.⁶ They indicate that if pH were a function of mean ionic activities, extrapolation of pK data would yield curves whose limiting tangents would approach the values of A obtained with their data on acetate buffer mixtures.^{18, 19}

Since the solutions employed in this work were not sufficiently dilute to warrant the application of the limiting law, an approximation of the Debye-Hückel theory was used. The method of extrapolation applied here gave limiting pK values for the buffer acids which showed fair agreement with the values obtained by other workers, with the exception of boric acid at 10° C. The pK value of boric acid, obtained by the procedure described previously, was about 0.04 unit lower than that obtained by Owen for the same temperature. The values of B in equation (4) varied with the temperature and the type of buffer acid.

SUMMARY

Using the pH values assigned to a standard phthalate buffer as reference, the pH values of acetate, phosphate, and borate buffers diluted with water and with sodium chloride solution have been determined at 10° C., 25° C., and 35° C. with a glass electrode in a cell with liquid junction. pK' and pK'' values have been computed from the appropriate pH data for the aqueous and saline buffer solutions, respectively. Employing the apparent linear relation between $(pK' + A\sqrt{\mu})$ and μ , limiting pK values of the buffer acids have been computed. Tests have been made of the degree of conformity of the pH scale adopted in this work with the limiting pK values and an approximation of the Debye-Hückel limiting law. Within the limits of experimental error the MacInnes-Belcher glass electrode, in conjunction with the Electron Ray Meter, gave accurate and reproducible pH values which were in agreement with the values obtained by others with the hydrogen electrode.

MEDICAL ILLUSTRATION

MOULAGE PROSTHESIS

CARL DAME CLARKE, PH.D., BALTIMORE, MD.

WITH ILLUSTRATIONS BY JOHN T. STRINGER, JR., AND CARL DAME CLARKE

THE art of face and body restoration is not new. In fact, the Hindus developed methods for the repair of nasal defects which today are considered good operative procedure in rhinoplasty. This was only one of their difficult plastic feats. According to Kazanjian, Rowe, and Young,¹ the literature of plastic surgery dates back as far as Celsus (25 B.C.) and Galen (A.D. 131-201). They call attention to Paul of Aegina (A.D. 630) and Branca (1442). They also mention Ambroise Paré (1541), Tagliacozzi (1545), Pierre Fauchard (1728), Bourdet Suerson and Delabarre (1820), Hullivan, Kingsley, Claude Martin, Nelaton, and Zeis (1900), and others. In 1875 Martin was the first to conceive of immediate prosthesis.

From the prewar plastic surgeons, Morestin, Lexer, and others, it will be noted that the medical and dental literature contains many articles, methods, and case reports concerning surgical and mechanical means of correcting pathologic deformities of the face. The horrible maiming effects of the first World War produced innumerable patients for surgeons, dentists, and moulage workers to treat. It was during war times that the art and science of prosthesis took gigantic strides forward.

In consideration of the fact that another World War is now in progress, it is obvious that there will be hundreds, if not thousands, of cases demanding prosthetic appliances.

In 1938 I published a book on the subject of *Molding and Casting*² in which I discussed previous work in moulage prosthesis in detail, as well as methods in present-day use for producing these prostheses. Since that time there have appeared on the market many synthetic plastics which lend themselves readily to the making of prostheses. It is my desire to describe herein the methods for making both a moulage prosthesis on what would ordinarily be a very simple case and a prosthesis for a more advanced case. Such work definitely falls on the scientific illustrator as well as the physician. The formulas for prosthetic work may be compounded by the worker, or the compositions may be purchased already prepared.

The physician can make a single mold and cast of the part to be reconstructed if the case is a simple one. From this mold he can make a reconstruction in wax of the missing part. Practically any dental laboratory can repro-

duce a synthetic plastic duplicate from this wax original. False teeth are made in the same manner by the dental laboratory from a mold supplied by the dentist.

Above all else the case in mind for reconstructive procedure should be considered carefully before any work is begun. The worker should determine whether it is more suitable for treatment by plastic surgery or by reconstructive prosthesis. It should be clearly understood that while the result of surgery may be more satisfactory, its application may involve danger and pain that is distributed over a period of weeks, with uncertain and often mortifying results. The prosthesis, while not a permanent cure, is without danger and involves no pain to the patient either in the making or in the wearing. For patients unable to withstand the debilitating effects of operative procedure, a prosthetic appliance is strongly recommended. I do not advocate the use of a prosthesis in preference to plastic surgery for the correction of facial defects. The case in question must be the deciding factor. However, it cannot be stressed too forcefully that plastic surgery alone should not be considered in every case.

Lederer³ writes that skin cannot be molded in the manner of clay; hence it is very difficult to produce a lifelike nose or ear by plastic surgery. The nose is constantly under the scrutiny of others, and it stands to reason that the patient would be no worse off without his nose or perhaps with a small adhesive dressing than he would with a few clumps of grafted skin, which at best would still be extremely conspicuous. Lederer maintains further that he, as well as other plastic surgeons, has been disappointed in the net result of his painstaking labors and, in a measure, feels guilty for having subjected his patients to operations which not only brought them great economic loss and suffering, but in many instances jeopardized their health and lives. They had scars remaining where tissue was grafted, spent many uncomfortable weeks in a cast (when Italian grafts were utilized), lost time from their work and in some instances had to accept primary failure owing to poor healing.

Van Dijk⁴ found that the ears he formed by plastic surgery were too bulky and not sufficiently erected, and that the fossa scaphoidea and the anthelix were not built up. He planned in his next patient to get the ear more erect through implants of cartilage, thus giving it a more shell-like appearance.

More and more the surgeon is beginning to recognize a substitute in the form of a prosthesis for certain plastic procedures. These two phases of the healing art are inseparably related. The future of restorative work, just as in the field of prevention, lies in the closest cooperation between physician and surgeon and the prosthetist.

Furthermore, if the surgeon is working with a prosthetist, the necessity of adequate surgical preparation for the application of an artificial restoration cannot be too strongly stressed. The failure of many prosthetic attempts is often caused by the unfortunate necessity of adapting restorative to areas of soft tissue which have been distorted and contracted by unnecessary

scar tissue and improper postoperative procedure. The success of a prosthetic restoration is in a great measure increased as the degree of mutilation is lessened.

The ability of the surgeon and of the moulage worker has much to do with the final result in either case. I am unable to criticize surgical technique but I am more familiar with the procedure of moulage making and the final prosthetic appliance. In my opinion these prostheses suffer from the same defects that are prevalent in most medical art work. In short, they lack artistic skill in execution and naturalness in its simplest form. The artificial appliance to the human face should, above all else, look realistically natural and individually suitable. The conspicuous errors of most poor prostheses are generally the result of a lack of artistic ability and appreciation on the part of the surgeon or prosthetist. These difficulties may be overcome by having the prosthetic appliance made by a skilled prosthetist in close cooperation with the plastic surgeon. Because the surgeon or dentist has considerable ability in surgery or moulage making does not necessarily mean that he is an artist. His ability or judgment to choose the correct feature in size and relative proportions to be fitted next to other adjoining features of flesh and blood may be lacking.

Another eventual stumbling block to the surgeon and dentist is the final coloring of the artificial part. It takes considerable experience in handling pigments and a natural color sense to blend perfectly the many different hues into the prosthesis to match the surrounding tissue. Hair, bristle brushes and airbrushes, pigments and pastes are often used for this purpose. The artist possessing this color sense yearns to "touch up" the average monochromed prosthesis which in its single hue is not natural. He desires further to eliminate the many false tones and shades of a modernistic pictorial nightmare. For the making of the best facial prosthesis close cooperation between the physician, dentist, and prosthetist is essential. Even the physician having little or no artistic ability can make acceptable prostheses of simple cases, provided he works in close cooperation with a dental laboratory.

In a simple case of prosthesis the first step is to obtain a mold or impression of the defective part. An agar composition is generally used for such work. This molding material may be purchased under the trade name of "Hydrocolloid" (Detroit Dental Mfg. Co.), "Dentocoll" (L. D. Canlk Co.), and others. A serviceable composition may be prepared from one of the formulas published in the articles listed in the references. If the worker is interested only in the results he obtains rather than in the materials he uses, he will find it more desirable to purchase the composition already prepared. The commercial preparation comes in a handy collapsible tube which is placed in boiling water for ten minutes. It is then transferred to lukewarm water and allowed to cool to a point where the tube does not feel uncomfortable when placed on the bare wrist. An agar composition should never be applied when it is so warm that it would be uncomfortable to the patient. This material should not set until it reaches a point ($+2^{\circ}$ C.) slightly above body temperature (37.5° C.). Even though the patient can withstand the heat, the material must

Fig. 1.—A. Front view of a defective area on the nose.
 B. A side view of the same area.
 C. The warm agar composition being applied to the nose directly from the tube.
 D. A front view of the agar mold in place just after setting.
 E. The agar mold being removed.
 F. The agar mold being filled with plaster of Paris, which sets to form the positive.

Fig. 2.—A The plaster impression after removal from the agar mold. The agar mold can be seen to the left. Part of the defect has been filled with additional plaster to allow a space for breathing. This is done with a soft brush and a plaster-water mixture.

B. The remainder of the defective area is filled with a wax composition (the formulas for which are in the text). A brush is used for applying the hot wax mixture. This is continued until the area is filled with the wax.

C. The wax is then carved down with an ordinary scalpel and shaped to follow the natural contours of the ala of the nose. A sharp, pointed probe is inserted into the wax from the inner side and the wax is removed. This wax will not adhere strongly to the wet plaster.

D. Showing the wax prosthesis being removed from the plaster nose.

E. The wax is then fitted into the patient's nose. If it fits perfectly it is turned over to a dental laboratory for reproducing into one of the modern synthetic plastics. A plastic is chosen to match the skin of the patient. This completed prosthesis is held in place by a solution of gum mastic dissolved in equal parts of alcohol and ether.

F. A side view of the patient with the prosthesis in place. E and F show the patient without any cosmetics over the prosthesis. The false area may be made to blend more perfectly with the skin by the use of "Covermark" or a similar cosmetic.

remain in place longer for sufficient cooling or setting time. When the tube has sufficiently cooled, its end is cut with a seissors and the material is squeezed over the afflicted part (Fig. 1c). In ten minutes the agar composition sets, after which it is removed (Fig. 1e). This mold should not be removed until it definitely feels firm. An entire ear can be cast in the same manner in a one-piece mold. This mold can then be filled with either hot wax or plaster of Paris. Wax should be used in making an ear as an intermediate step for a final rubber or synthetic plastic prosthesis. However, in considering the patient in the illustration (Fig. 1), it is best that the nose in this case be made in plaster of Paris, for the defective part must be modeled in wax on the plaster. This is done because the wax will separate readily from the wet plaster.

After the plaster nose has set, it is removed from the agar mold (Fig. 2a). Additional plaster is applied with a soft brush to the area represented by the opening in a normal nose for breathing. This will create the opening for breathing in the prosthesis. A brush is then dipped in a hot wax composition and applied directly over the defective area (Fig. 2b).

A wax composition suitable for this purpose is as follows:

	<i>Parts by weight</i>
Paraffin (62° C.)	10
Rosin	8
Carnauba wax	1

A ready-made wax may be purchased from dental supply stores. After the wax has set, it is carved with a pocketknife, scalpel, dental or sculptor's tool until it takes the shape of a normal nose (Fig. 2c).

A sharp, pointed probe is then inserted from the inner surface of the wax ala and with a slight pressure it should separate from the wet plaster (Fig. 2d). This wax piece can be tested on the patient (Figs. 2e and f). If it fits perfectly it is turned over to a dental laboratory to be made into one of the synthetic plastics, such as "Vernonite," "Crystalex," and "Luectone." Of course, shade should be chosen which matches the patient's skin as nearly as possible. If in the wax stage the prosthesis does not fit, it can be adjusted or changed so that it will fit the patient.

It is not advisable for the average physician or surgeon to attempt to do the final stage in the making of a prosthesis, since the dental laboratory is more fully equipped for such work and its charges are reasonable. After the synthetic plastic part is finished, the edge that comes in contact with the skin is painted with a solution of gum mastic dissolved in equal parts of alcohol and ether. The prosthesis is then put in place and held there with a finger until the solvent has evaporated and caused the gum mastic to hold it in place. This takes less than a minute in most instances.

A more complicated case (Figs. 3, 4, and 5) requires a greater knowledge in making prosthetic appliances. This case was a patient of the late Dr. A. Russell, whom I assisted in developing the prosthesis.

The first procedure was to obtain a plaster cast of the face in its original condition. Tubes were inserted in the nasal cavity and gauze was placed around

the tubes. The mold was then made of agar and reinforced with a plaster shell or mother mold (Fig. 3c-f). From this mold the plaster positive or cast which showed the complete facial defect was made. In this case ordinary gray plasteline was used to model a nose on the plaster ease (Fig. 4b). This, of course, requires artistic ability or training. However, the modeling of a nose is not essential, for a mold may be made of a living person who has a well-formed, if not an idealistic, nose. This person must be of the same type and general proportions as the patient. The cast from this second mold may be trimmed to fit into the open space on the plaster mask of the patient. The edges between the two casts may then be smoothed out by the use of plasteline.

From the modeled nose a mold was made of the reconstruction only (Fig. 4c) and a red wax impression was made from the mold (Fig. 4 c-g). The red wax cast is later removed from a piece mold; it sometimes requires boiling water to melt it. The subject of agar and wax compositions has been discussed.

Upon its removal from the mold (Fig. 4c), the back of the cast was modeled or carved into the shape (Fig. 4d). An extra knob was added to the wax impression as a support for attachment to the artificial palate which had been made previously.

After the wax impression was modeled or carved to the desired shape to suit the mechanical necessities of the cast, a piece mold of the entire cast, including front and back, was made (Fig. 4e). From this mold other red wax casts seen in *d* could be made. This is the same piece mold that is to be used to cast the final impression, provided the red wax cast fits the patient. Tests to determine the snugness of the fit were made on the original plaster cast of the face after the plasteline nose had been removed. Such tests were also made by putting the wax impression on the patient (Fig. 4f and g). The final impression was then cast.

The material used for this final cast should be considered seriously. Numerous substances such as gelatin (Henning's method, described by Salamon; also elaborated on by Zinsser, Pont, Bereowitsch;⁵ Kazanjian, Rowe, and Young¹) and light metals, such as aluminum, have been used. Plastics, such as vulcanite or vulcanized rubber (not vulcanized latex) and celluloid compositions have been employed as positive casting materials.

The materials used in the past have been discussed fully in the articles listed as references. In my opinion the best materials for making a prosthesis to be worn on the face are the synthetic plastics previously discussed, and vulcanized latex. In comparison with rubber the synthetic plastics have one serious drawback when they are considered for large prostheses as, for example, an entire ear; they are hard and rigid, and somewhat heavier than rubber.

In making a moulage prosthesis of rubber, vulcanized latex, powdered fillers, and coloring agents are used. First, the powder is added to the flesh-colored latex until the desired consistency is obtained. Permanent water-soluble aniline dyes having a neutral or alkaline reaction are used for coloring the vulcanized latex to a flesh tint. The latex is then poured into a plaster mold and allowed to remain until the plaster absorbs enough water from the vulcanized latex to

cause a deposit of sufficient thickness. The surplus is then poured out. The latex can also be painted, layer by layer, into an agar, wax, or metal impression of a duplicate of the part to be replaced. Each layer of the rubber composition sets within a few minutes, after which another layer is applied. A celluloid solution may be poured or painted over this rubber to give it additional support and serve in a manner similar to the cartilage in the ear. The liquid celluloid may be made by dissolving scrap celluloid in butyl acetate. After the celluloid has set, more rubber may be painted over it, thus increasing this inflammable material in rubber. In other words, the rubber takes the place of flesh and the celluloid takes the place of cartilage. After drying, the resulting rubber cast is removed from the mold. Gentle heat speeds the setting time of such rubber casts.

It is far more difficult to trim and patch rubber impressions than to do the same work on wax or plaster impressions. Such trimming as is necessary must be done with very sharp wet knives. A wet blade cuts rubber more easily than a dry blade. Because of the difficulty of patching rubber positives, as many corrections as possible should be made on the mold. Another method is to obtain a thoroughly trimmed and patched wax cast of the individual, and make a second mold over this impression in any metal, except copper or zinc, by electrodeposition of the metal. Nickel may be electroplated on the wax, then copper, and then nickel again, thus increasing the copper between two layers of nickel. The metal mold is then used for casting rubber impressions. In most cases an unlimited number of positives may be obtained from a single mold.

In making a prosthesis of a hand, agar composition can be used to secure a one-piece mold. Wax is poured into the mold to obtain a wax positive. A one-piece plaster mold is made over the wax, and the wax is removed from the plaster with boiling water. Vulcanized latex is poured into the one-piece dry plaster mold to obtain a rubber hand. By this method even the pores of the skin are duplicated.

Vulcanized latex, which is sold under the trade name of "Vultex,"* is undoubtedly one of the best materials to use for making large artificial parts to be worn on the human body. It has many advantages: (1) Vulcanizing agents are unnecessary. (2) It sets in a closed plaster mold into which it may be poured through a funnel-like opening. (3) A separating medium is not necessary, as vulcanized latex does not stick to plaster of Paris. In fact, the plaster absorbs the water from the mixture and causes it to set. (4) Colors, such as carmine (acid-free red water color in tubes), may be incorporated in the vulcanized latex to give it a flesh tone before it is poured. There is enough yellow in the set Vultex to give it a fleshlike tone when the carmine is added. Zinc oxide may be added to the liquid vulcanized latex to prevent the resulting prosthesis from becoming a too dark yellow. (5) Shrinkage does not occur as much in highly concentrated vulcanized latex mixtures as in thin mixtures. Unless the mold is tamped or jarred during the pouring, the resulting prosthesis may be partially hollow. Fillers can be added to make the mixture thicker.

*This material may be obtained from R. W. Edmonds, Manufacturers' Agent, 401 Water Street, Baltimore, Md.

These increase the tendency toward a hollow casting. Of course, large prostheses, such as hands, should be hollow.

Should light metals, such as aluminum and silver or their alloys, be chosen for the prosthesis, the metal may be shaped to the correct form in a swedge mold or die and counter die. These may be of plaster. The formation of the metal must be taken in easy stages, with numerous counterdies of different levels to prevent tearing of the metal. The metal is then annealed between each stage.

A

B

FIG. 5—A. If the red wax nose fits perfectly the same mold used for casting the red wax may be used for casting the final positive material. In this illustration the final cast has been attached to the spectacles. An artificial mustache has been attached to the final cast.

B A front view of the same patient.

Metal prosthesis is considered inferior to other substances for attachment to the human body. However, should the worker care to pursue this subject he may find valuable information in the dental literature.

I have discussed moulage prosthesis more fully in the book, *Molding and Casting*. However, since the publication of this book the Mayo Clinic has published two articles on the subject^{6,7} which give specific formulas for compounding rubber prostheses from vulcanized latex. I find that a single formula does not fit every case. If the worker understands his materials, he is likely to vary them to fit individual cases.

The final prosthesis is fixed to the patient with the gum mastic solution previously mentioned or with some mechanical device as eyeglasses or eyeglass frames. The prosthesis in Fig. 5 was riveted to the nosepiece of the eyeglass frame.

Sometimes it is desirable to touch up a prosthetic appliance with additional color because its monochrome effect may not be entirely realistic. If the original

is in celluloid, a small amount of transparent oil color (phototinting color) may be mixed with acetone to be used in the coloring. This acetone softens the celluloid sufficiently to allow some of the dye to penetrate the surface without destroying the skin effect. If a synthetic plastic is used, its solvent can be incorporated with a transparent oil color in the same manner to give additional tints. If the prosthesis is in rubber, benzene or carbon tetrachloride may be incorporated with the transparent oil color. These solvents cause the prosthesis to be slightly sticky immediately after they are used, but they dry in a short while. The worker should realize that to do this work successfully a certain amount of practice and skill is necessary. He should test his tinting ability on objects that have no value. It is possible that his first attempts at prosthetic work will be failures. The objects should be saved to be used in testing other processes in the work, such as tinting.

After the prosthesis is put in place on the patient, cosmetics can be used successfully in making the prosthesis blend with the surrounding tissue. The preparation called "Covermark"* is excellent for this purpose. Any small cracks between the prosthesis and the surrounding tissue may be filled with a putty made by mixing vanishing cream and talcum powder. However, if such cracks are quite obvious it is logical that the prosthesis should be made over. A well-made prosthesis should not be detected at a distance of three feet under ordinary lighting conditions, such as daylight in the average room or artificial light at night.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

PURPURA, The Present Status of Thrombocytopenic, Wiseman, B. K., Doan, C. A., and Wilson, S. J. J. A. M. A. 115: 8, 1940.

No single theory for the production of essential thrombocytopenic purpura adequately accounts for all the known facts relating to this disease; however, that of splenic thrombolytic appears to violate the fewest.

In differential diagnosis aspiration of bone marrow to rule out leucopenic leucemia, aplastic anemia, pernicious anemia, and neoplasia is at times essential. Historical facts relating to drugs and present or recent contact with certain infectious diseases are most important.

In essential thrombocytopenia the only measure known that will restore the platelet level is splenectomy. The more pronounced the bleeding tendency the more urgent the indication for surgery.

No case of symptomatic thrombocytopenia, regardless of the degree of bleeding, should be submitted to surgery.

LEAD, Absorption and Intoxication in Man Unassociated With Occupational or Industrial Hazards, Hansmann, G. H., and Perry, M. C. Arch. Path. 30: 226, 1940.

The analysis of the data obtained may be divided into facts derived from the data and suggestions for consideration contained in the data.

A. Facts derived from the data:

Examinations of tissues for lead absorption were made on 48 bodies, the ages of which ranged from 11 weeks' gestation to 93 years of age.

The amount of lead in the ribs varied from 23.058 mg. to 0.00 mg. per hundred grams.

The amount of lead in the liver varied from 21.033 mg. to 0.00 mg. per hundred grams.

The lead content is expressed in milligrams per hundred grams of dried tissue.

There appeared to be no relationship between the amount of lead absorbed and the age, except that those subjects containing no lead were either fetuses or children under 12 years of age.

The amount of lead in the liver may exceed that in the rib during prolonged metabolic disturbances, severe infections, and less acute progressive fatal illness.

A mother who has absorbed lead will excrete increasing amounts of lead during gestation, the excretion of which parallels the skeletal growth of the fetus.

The analysis of entire fetuses, the ages ranging from 11 to 24 weeks' gestation, revealed lead in 62.5 per cent of them. The amount in 25 per cent of these bodies may be considered hazardous.

Eighty per cent of fetuses from 4½ months to term had lead in the rib or the liver or in both organs.

All subjects over 12 years of age or 90 per cent of those between birth and 93 years of age revealed evidence of lead absorption.

A review of the results recorded in the literature with which our results were integrated, has established by spectrographic, colorimetric, and titrametric methods that lead absorption is a normal consideration.

The cases were all drawn from Milwaukee and its vicinity.

B. Suggestions for consideration contained in the data:

Lead absorption may act as an unrecognized factor in various diseases in persons who cannot trace their exposure to lead.

Aged persons, who frequently lose, often quite rapidly, upward of 50 per cent of their skeletal calcium, may suffer symptoms of intoxication from the lead which is concurrently released, provided the skeleton is heavily leaded.

Women may suffer from lead intoxication during gestation, owing to the fact that much lead is released from a heavily leaded skeleton during gestation. This may be responsible for some of the anemias closely resembling pernicious anemia which occur during and shortly after pregnancy.

The fetus is likewise exposed to lead hazards, which may result in intoxication of the fetus or expulsion of the fetus as a result of the action of lead on the uterus.

The patient with a heavily leaded skeleton may suffer from symptoms of lead intoxication during uncontrolled metabolic diseases, severe infections, or prolonged, progressive illness, owing to the fact that lead is mobilized from the skeleton and fixed by the organs.

Lead may be an important cause of abortion during the first three months of gestation.

The development of the fetal skeleton may protect the fetus by withdrawal of lead from the circulation.

Lead absorption may become an individual problem and the concern of every physician.

JAUNDICE, Renal Lesions Associated With Deep, Ayer, D. Arch. Path. 30: 26, 1940.

In infants with long-sustained uncomplicated jaundice, due to congenital atresia of the bile ducts, renal lesions occur without producing oliguria. These lesions consist of focal exudative changes, obstruction of tubules by casts, and phagocytosis of cast material by epithelial cells. These lesions are duplicated in the kidneys from patients with transfusion reaction and the hepatorenal syndrome.

SULFANILAMIDE, A Micro Bedside Test for Determination of, in Body Fluids, Schoeffel, E. W. J. A. M. A. 115: 122, 1940.

A. Place a drop of the body fluid under examination (approximately from 0.01 to 0.05 c.c.) with calibrated pipettes of the blood pipette type in the depression of a hanging-drop slide. (The liquid may be dried by air current. If the material must be shipped, the dried substance is covered with a drop (from 0.050 to 0.075 c.c.) of liquid petrolatum U.S.P. and the cover slip fastened on with a seal.) Place all slides on a clean white towel.

B. Add 0.02 c.c. of 4 normal hydrochloric acid and 0.02 c.c. of 10 per cent trichloroacetic acid to the material in the depression. Break up and stir thoroughly with a glass thread. For total sulfanilamide heat over an alcohol lamp to near dryness and repeat step B.

C. Add 0.03 c.c. of 0.1 per cent sodium nitrite solution and stir the mixture thoroughly for thirty seconds with a glass rod (with amounts of free sulfanilamide in excess of 20 mg. for 100 c.c. use 0.05 c.c.).

D. Add 0.02 c.c. of a solution containing 0.1 per cent ammonium sulfamate and stir the solution thoroughly (for larger amounts of sodium nitrite use corresponding amounts of the sulfamate solution).

E. Add 0.02 c.c. of 0.4 per cent aqueous solution of N(1-naphthyl)-ethylenediamine dihydrochloride (Marshall's reagent; the solution should be kept in a dark brown bottle and only enough made up to last two days). Stir the mixture thoroughly.

F. Prepare standards (as described under standard reagents and apparatus to be used for the test) containing 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 12.5, and 15 mg. per hundred cubic centimeters. If testing for sulfanilamide, use sulfanilamide in the standards; if testing for sulfapyridine or sulfathiazole, use sulfapyridine or sulfathiazole standards, respectively. Such standards are good for one week if kept in an icebox and away from direct light. The standards may be conveniently prepared by carefully diluting a larger amount.

G. Insert in the depression containing the now red solution a strip of filter paper and let the liquid spread by capillary action over one end of the paper (precipitated protein material does not interfere with the test). Compare the unknown samples with the standards. The developed color depends upon the drug used. It is necessary for the technician to know which of the sulfanilamido derivatives were used. It is important to know whether other therapeutic agents were also used. Especially with specimens of urine, a slight color varia-

tion may be noticed, depending upon various diazotizable substances. Since no fractions are to be determined and only round figures are given (2.5, 4, and 7.5 mg. per hundred cubic centimeters), no strong interference exists. The color on the filter paper will slowly fade but will hold distinctive and discernible hues for a period of days when compared with standards prepared on the same day and kept under the same conditions. Actual color charts may also be prepared to facilitate the determination at the bedside. In general for ease of reproduction the final amount of liquid in the depression should not exceed the approximate amounts of from 0.125 to 0.150 c.c.

HEPATIC DISEASE, Clinical Value of Determination of Cholesterol Esters of Blood in,
Greene, C. H., Hotz, R., and Leahy, E. Arch. Int. Med. 65: 1130, 1940.

The value for cholesterol in the blood of adults varies between 150 and 230 mg. per hundred cubic centimeters, whereas the combined cholesterol (esters) varies between 60 and 120 mg. The ratio of the combined to the total blood cholesterol is quite constant—between 40 and 52 per cent.

In this series, patients with evident hepatic damage had a decreased amount of combined cholesterol in the blood. This decrease was sometimes, but not always, associated with a decrease in the total cholesterol. The ratio per se was not of as great diagnostic usefulness as was the total amount of esters present in the blood.

In uncomplicated obstructive jaundice the combined cholesterol tends to rise in proportion to the rise in total cholesterol; but in hepatic disease the cholesterol esters tend to disappear from the blood regardless of the behavior of the total cholesterol.

In a given case a progressive decrease in the values for the combined cholesterol of the blood signifies a poor prognosis, whereas a progressive increase signifies a good prognosis.

The determination of the combined cholesterol of the blood is of great value in determining the prognosis of surgical treatment of patients with disease of the biliary tract.

TISSUE: Hamdi's Preserving Solution, Cambel, P. Arch. Path. 29: 813, 1940.

The specimen to be preserved is fixed in a 10 to 20 per cent dilution of the 40 per cent stock solution on the market. The larger and more solid the specimen (brain, liver, large spleen, large tumor) the higher the percentage of stock solution that may be used. After the specimen has been thoroughly fixed and prepared, it is left in running tap water for at least twenty-four hours; then it is placed in a highly hypertonic (about 50 per cent) salt solution prepared with clean tap water. Here it is left for two to five days. The hypertonic salt solution penetrates the organ, drives out the formaldehyde solution, causes a slight swelling, which removes the shrinkage due to the formaldehyde solution and increases the weight of the specimen, so that the lungs, for instance, do not float when placed in the preserving fluid. It helps, moreover, to prevent the growth of molds. After the organ has been rinsed in running water, it is placed directly into Hamdi's solution, the formula of which is as follows:

Sodium sulfate (pure)	5 Gm.
Salt (pure)	100 Gm.
Clear tap water containing no organic impurities	1,000 Gm.
Glycerin	50 Gm.

The solution is clear, practically colorless. It may be yellowish if the glycerin is yellowish. Icteric organs sometimes give it an icteric tint. After a couple of years it may become slightly yellowish, especially when the specimen is exposed to much light.

A few drops of a saturated camphor solution in 96 per cent alcohol is added. The white precipitate that forms is dissipated by superficial stirring with a glass rod. Then the glass cover is sealed on the container.

If the seal loosens and molds form, and even if the color of the specimen is spoiled on account of the molds, it is sufficient to leave the specimen for half an hour to a few hours in running water and in a jar into which a few crystals of potassium permanganate have been placed. The organ is then rinsed in running water, treated with salt water or not, replaced in fresh Hamdi solution, and the jar resealed.

The advantages of Hamdi's solution are: It does not necessitate a preliminary treatment of specimens with alcohol as with most of the preserving solutions now in use. It preserves the specimens practically in their natural condition; it does not destroy the red blood corpuscles.

HYPERTENSION: I. Effect of Nephrectomy Upon, Associated With Organic Renal Disease, Schroeder, H. A., and Fish, G. W. Am. J. M. Sc. 199: 601, 1940.

Seven patients exhibiting arterial hypertension associated with organic renal disease have been subjected to nephrectomy. Two were markedly improved, and 2 slightly improved, but all remain actually or potentially hypertensive.

This form of therapy may prove of benefit, but, it seems, only in patients in whom the existence of hypertension is of short duration and in whom arteriolar sclerosis of the other kidney is not advanced. Its use is limited, therefore, to a small number of individuals.

As criteria for selection of cases for this form of therapy the authors suggest:

1. The onset of hypertension should be known to have occurred recently (arbitrarily two years).
2. The renal lesion should be confined to one kidney and should be of such a nature that diminution of function has occurred in that kidney.
3. Renal functions, as measured by the ability of both kidneys to concentrate urine and by the test of the clearance of urea, should be within normal limits.
4. Retinitis should be absent, and changes in the caliber of the vessels of the retina should be minimal.
5. Arterial pressure should be persistently elevated.

II. ARTERIAL HYPERTENSION, The Role of the Kidney in the Pathogenesis of, Dicker, E. Am. J. M. Sc. 199: 616, 1940.

For the kidneys to be able to cause hypertension their circulation must be restricted; all the other renal and urinary manifestations are secondary, independent, and incapable of playing a part in the production and maintenance of the hypertension.

III. ESSENTIAL HYPERTENSION: Comparison of the Hypertensive and Non-Hypertensive Phases Following Coronary Thrombosis, Gross, H., and Engelberg, H. Am. J. M. Sc. 199: 621, 1940.

An analysis is presented of 100 autopsied cases of hypertension and severe coronary artery disease studied for the effect of the blood pressure on the subsequent course. All the patients had cardiac hypertrophy and marked myocardial damage.

Ninety patients had chronic congestive heart failure. The high incidence of heart failure is partly due to the type of patient admitted to Montefiore Hospital. The onset of heart failure frequently followed an acute coronary occlusion. This occurrence was so striking that in cases of chronic coronary sclerosis, when heart failure begins rather abruptly, a silent coronary occlusion should be suspected.

There were 24 persons with terminal acute coronary closure and in these the course of blood pressure was known for at least one year prior to death. Fifteen had hypertension persisting up to the final closure, 7 had low blood pressure for several months prior to the closure, and in 2 the blood pressure varied in the preceding year.

Analysis of the course of blood pressure subsequent to acute coronary occlusion was made. Eighteen persons had persistent hypertension (after recovery from the initial drop), 12 had permanently low blood pressure, and 10 had variable pressure. The same variations in the course of hypertension occurred when no acute occlusion could be diagnosed clinically with certainty.

Twenty-one of the 100 patients died suddenly. Many of these had the clinical picture of acute coronary thrombosis, but in only four of this group was a terminal closure found following coronary thrombosis.

The subsequent blood pressure in hypertensive patients following coronary thrombosis had no effect on longevity, or on the occurrence, severity, and duration of heart failure. Neither was there a definite relationship between the course of blood pressure and the heart weight and the duration of failure. Physiologic factors undoubtedly play a role adjusting the work of the heart to a restoration or a permanent fall in the blood pressure. These factors have been discussed.

SULFANILAMIDE, Relation of p-Aminobenzoic Acid to the Mechanism of the Action of, Woods, D. D. Brit. J. Exper. Path. 21: 74, 1940.

Yeast extracts contain a substance which reverses the inhibitory action of sulfanilamide on the growth of hemolytic streptococci.

Examination of the chemical properties of this substance and its behavior in growth tests suggested that it might be chemically related to sulfanilamide.

p-Aminobenzoic acid has high activity in antagonizing sulfanilamide inhibition.

There is strong circumstantial evidence that the yeast factor may be p-aminobenzoic acid.

SULFANILAMIDE, The Inhibition of the Action of, in Mice by p-Aminobenzoic Acid, Selbie, F. R. Brit. J. Exper. Path. 21: 90, 1940.

The experiments described show that the therapeutic action of sulfanilamide in mice infected with streptococci can be inhibited by p-aminobenzoic acid in the same way as its antistreptococcal action is inhibited in bacterial cultures. The mechanism of its action in vivo would therefore appear to be similar, if not identical, to its action in vitro. Woods (1940) has suggested that p-aminobenzoic acid or some similar substance is essential for the growth of bacteria and that its utilization can be blocked by sulfanilamide. Many of the discrepancies which have arisen in the course of the work on the sulfanilamide drugs can be explained as due to variations in the amount of the essential substance available in the bacterial cells or in their environment (blood stream, tissues, etc.). It would also appear probable that the lag phase in the action of sulfanilamide coincides with the slow exhaustion of the essential substance.

TRICHINELLA SPIRALIS, Early Mild Infestation With, Andes, J. E., Greene, R. A., and Breazeale, E. L. J. A. M. A. 144: 2272, 1940.

Of ten patients believed to have been infested with *Trichinella spiralis*, all but one gave a history of eating pork from one to three days before the onset.

The condition of eight of these patients was diagnosed within the first three days of the onset. The most common symptoms were malaise, abdominal discomfort, fever, headache, and edema around the eyes. All showed a definite eosinophilia and all tested gave a positive skin reaction and trichinella antigen. Administration of tetrachlorethylene was followed by complete and immediate recovery.

The two patients consulting the authors six and seven days after the onset contracted muscle pain and tenderness; the third patient showed a fairly long drawn out convalescence.

The eosinophile count of the blood was shown to rise continually during the day, being highest in the evening.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

The Author Publisher Printer Complex*

A WELL-WRITTEN booklet on the preparation of manuscript, correction of proof, and related aspects of writing and publishing a book, the title might more accurately have been "Advice From a Publisher to His Authors."

The author who has read this book will have a much clearer understanding of the problems which his publisher must solve and the decisions which he must make, many of which might otherwise have appeared unjustified.

This small work should be highly recommended to all who contemplate writing a book or an essay. It will be enjoyed equally by those who have written in the past.

Directory of Medical Specialists†

ENTERPRISING firms have in the past attempted to prepare reference catalogues of physicians in the various specialties in the United States. Some have catalogued any and all who were willing to pay for a copy of the finished book, while others have attempted some manner of selection, such as recommendation by recognized leading physicians in different localities.

None of these has been satisfactory. Those who have had occasion to investigate the qualifications of doctors in distant localities have had to rely chiefly on the sparse information available in the Directory of the American Medical Association.

With the advent of certification in the specialties after adequate examination by official boards, a satisfactory standard for inclusion in a directory of this sort has for the first time become available. The Directory of Medical Specialists includes all persons in the United States and its possessions and in Canada who are diplomats of the official boards in the various specialties. The Directory is, therefore, authentic and reliable. The Board of Editors comprises the secretaries of the several specialty boards.

Approximately 14,400 diplomas certified by the twelve special American boards and one of the two affiliate boards are listed. Cross indexing, geographical and alphabetical, is adequate.

Twice on the day of arrival of the book the reviewer had occasion to use it, thus promptly discovering that it adequately fulfills its purpose.

PROGRESS

CLINICAL ASPECTS OF SULFAPYRIDINE THERAPY*

ROBERT A. KILDUFFE, A.M., M.D., F.A.S.C.P., ATLANTIC CITY, N. J.

PNEUMONIA has long been recognized as one of the more important of the lethal afflictions of mankind.

From Hippocrates,¹ who wrote of the importance of the "cough" of the sputum; and Aretaeus,² who began his discussion with these words: "Animals live by two principal things, food and breath (pneuma); of these by far the most important is the respiration, for if it be stopped, the man will not endure long but immediately dies"; on to Osler's classic description of this disease as "Captain of the Men of Death," pneumonia has attracted the attention of the physician and investigator throughout the ages.

But despite the work of innumerable investigators, pneumonia for centuries remained a disease before which the physician stood almost without resource; for progress in medicine, though steady and persistent, often seems intolerably slow.

Not until the advent of type-specific immune sera was there any marked advance in the therapy of pneumonia, and great though this discovery was, the victory was but partial. For, though it was learned that the race of pneumococci embraced 32 serologically separable types—perhaps more—for but relatively few of these did it seem possible to develop therapeutically effective antisera.

Attention was focused, therefore, upon developing a specific and effective chemotherapy; not necessarily what Ehrlich defined as a "*therapia sterilisans magna*" but some drug which per se, or through its derivatives, might offer definite and demonstrable hope for the consistently efficient management and control of pneumonia in all its varied bacteriologic entities. Thus, for many years, this drug or that, this compound or the other, flourished for a while and, under the acid test of time and trial, passed on to obscurity.

*From the Laboratories, Atlantic City Hospital.

Appreciation of great discoveries in medicine is more often gradual than dramatically sudden; indeed, they often pass relatively unnoticed until fortuitous circumstances bring them to light.

Thus it was with the "Quellung" reaction, described by Neufeld, which, though now an essential prerequisite to the intelligent treatment of pneumonia, lay dormant for a quarter of a century. Thus it was also with the discovery of sulfanilamide which, though elaborated in 1908, remained with all its remarkable qualities unheralded and unsung until comparatively recent times.

As its widening range of capabilities became more and more apparent, it was inevitable that attempts should be made to find in sulfanilamide, or in its derivatives, some drug which, effective against the pneumococcus, would also possess a chemotherapeutic index rendering it safe for clinical use.

It is needless to list the innumerable substances synthesized in these attempts. If the resultant compound proved effective against the pneumococcus in experimental infections, all too often the chemotherapeutic index—the margin between the toxic and the therapeutically efficient dose—was too small for safety.

It was not until the report of Whitby³ in 1938—it seems difficult to appreciate that it was only two and a half years ago—of the apparent efficiency of 2-sulfanilylaminopyridine, a substance elaborated by Ewins and Phillips in England, that there seemed some promise that the long-sought goal had been reached.

Whitby first reported the effectiveness of this compound against the pneumococcus, but it was the report of Evans and Gaisford⁴ in the same year which first showed its application to the treatment of lobar pneumonia. Since then innumerable reports concerned with it have been written, with the end not yet in sight.

Though efficient chemotherapy for pneumonia seems in large measure to have been at last achieved, oddly enough we are still largely at a loss for a satisfactory explanation for, or a definite understanding of, the mode of action of sulfapyridine upon the pneumococcus. That it has an action the clinical response following its administration in pneumonia proves beyond dispute. That this clinical effect is dependent upon some mechanism yet to be explained is equally clearly shown by various laboratory and experimental studies.

It is well recognized that bacterial infection is primarily dependent upon the concomitant influence of several factors, some of primary and essential, others of ancillary, importance.

In addition to the inherent and acquired resistance of the patient and his tissues, the virulence, aggressiveness, and toxicity of the invading bacteria must all be taken into account. Only when a suitable balance or imbalance between these varied factors is present does infection occur.

When chemotherapy is effective, it is logical to look for the reason in its effect upon bacteria, and it is ordinarily to be expected that that effect will be mainly, if not entirely, bactericidal.

But the action of sulfanilamide and its derivatives, sulfapyridine among them, upon the pneumococcus is not bactericidal but apparently merely bac-

teristatic. For while the pneumococcus remains alive and propagates itself in the presence of sulfapyridine, there is a definite lag in its growth, which appears to be definitely inhibited, establishing the drug as bacteriostatic rather than bactericidal.

We do not know how this bacteriostatic effect comes about; for while there are many theories and hypotheses, all must be regarded as speculative and unproved. This is, perhaps, not altogether surprising in view of the fact that the pneumococcus itself still remains in many respects somewhat of a bacteriologic puzzle.

Perhaps the most important advance toward an understanding of the pathogenicity of the pneumococcus was the discovery that its most important constituent, and the one most largely concerned in its action upon the tissues, resides in its capsule, the "specific soluble carbohydrate substance," as it is now called. Unfortunately, this substance is soluble and passes into the blood stream. In many respects the severity of the pneumonic infection is rather directly proportionate to the concentration in, and distribution of, this substance by the circulation.

We are still uncertain of the relationship between this capsular polysaccharide and the invasiveness of a particular strain of pneumococci. We do not know whether the polysaccharide may properly be regarded as the pneumococcus toxin, or whether the pathogenic ability and toxicity of the pneumococcus resides solely in its capsular substance or in part—or at all—in its somatic protein substance. These are but a few of the problems to be solved.

Granting the bacteriostatic effect of sulfapyridine upon the pneumococcus, what, if any, is the relationship and the importance of this effect to the clinical results obtained?

Is the bacteriostatic effect the ultimate explanation? Or does the bacteriostasis simply allow time for mobilization of the defensive mechanism of the patient so that the neutralization of toxic substances and the elimination of the pneumococcus by phagocytosis, bacteriolysis, and the contributory effect of opsonins may be effectively exerted?

While any or all of these may take place, or may be in some measure determined by bacteriostasis and thus play some part in recovery, it is difficult to believe that this is the whole story.

In view of the importance of the specific capsular polysaccharide in determining the pathogenicity and toxicity of the pneumococcus, does any evidence suggest a relationship between the clinical effects of sulfapyridine and some possible effect upon the capsular substance, its elaboration, or its concentration in the blood stream? May sulfapyridine prevent or inhibit the formation of capsular substance or in any way immobilize it or render it innocuous or relatively so? Any such assumption must postulate an effect upon the pneumococcus capsule consequent upon exposure to sulfapyridine. Is there any evidence suggesting such a possibility? Here at last we find a question to which a conditioned and reserved answer may be made, based upon observations by various workers in connection with pneumococcus typing by the Neufeld method.

As everyone now knows, type specificity is demonstrable in the Neufeld method by the occurrence of the Quellung reaction evidenced by a marked swelling of the pneumococcus capsule when brought in contact with its homologous immune serum.

Failure to type the pneumococcus may be dependent upon technical errors when the method is applied by those unskilled in bacteriologic procedures; it may be influenced by dissociation of the pneumococcus; certain types if not thereby shown to be identical, certainly show cross reactions with typing sera; failure to secure type differentiation may suggest there are more than 32 types; there is also definite and cumulative evidence that pneumococcus typing in the presence of sulfapyridine is not infrequently difficult and unsatisfactory, if not impossible.

It must be admitted, however, that the relationship of sulfapyridine to anomalous results in pneumococcus typing is still *sub judice*. Bullova, Osgood, Bukantz, and Brownlee,⁵ from a study of pneumococcus-infected marrow cultures, report that while pneumococci exposed to sulfapyridine may become distorted, develop long chains, and stain irregularly, they suffer no loss of capsule or type specificity.

Now, as the Quellung reaction upon which pneumococcus typing depends arises from an effect upon the capsule, if this effect is interfered with in the presence of sulfapyridine, it seems logical to postulate some effect of the drug upon the capsule. If this be so, then various speculations arise as to some possible relation to the specific capsular substance.

But again we encounter a maze of speculative hypotheses. Does sulfapyridine affect the permeability of the capsule, and, if so, would this increase the vulnerability of the pneumococcus to antibodies such as opsonins and hence to phagocytosis? Is the effect something other than some change in permeability? Does some change occur in the reactive ability of the capsule, and, if so, what is its nature? Or is there some alteration in the elaboration, mobilization, or solubility of the specific capsular substance? To none of these queries can a satisfactory or definitive answer yet be given.

It is both logical and empirical to assume a definite relationship between the chemotherapeutic efficiency and the concentration of the drug in question. As this has been shown to be in a large measure true of sulfanilamide, it was logical to assume that it must also hold true for sulfapyridine, the effective concentration in the blood being generally regarded as between 4 and 10 mg. per 100 c.c., with the latter as the upper limit of safety. However, there are fairly definite indications that suggest a lack of definite correlation between the blood concentration of sulfapyridine and the clinical result consequent upon its use in pneumonia.

Illustrative of such reports is that by St. George, Kraetzer, and Magee⁶ of a carefully controlled series of 50 unselected cases. Their tables show concentrations of sulfanilamide in the blood varying from 1.3 to 6.5 mg. per 100 c.c.; the latter being the highest they obtained. But, despite this variation within fairly wide limits, there was no apparent correlation with the ultimate clinical result nor was the incidence of recovery in any way definitely proportionate to the blood concentration.

It is recognized that the blood concentration is affected by factors such as nausea and vomiting, influencing the rapidity and degree of absorption, and also perhaps by others not yet clearly understood that may affect the degree to which the drug is acetylated or conjugated. Nevertheless, this and other similar reports are significant, even though at first they seem merely to further beloud an already obscure picture.

The intelligent consideration of any therapeutic agent must embrace not only its therapeutic effects, but also its nonspecific and undesirable by-effects; in other words, its toxicity for the human being.

Here we enter upon somewhat less uncertain ground for, though we may not always possess a clear explanation for their occurrence, we have cumulative and increasing clinical evidence of definitely toxic and undesirable by-effects of sulfapyridine for which it is necessary to be on guard and which, in any degree, it is highly desirable to avoid.

Remembering that sulfapyridine is synthesized from aminopyridine, it is not altogether amazing that there is some reason to believe that certain individuals, fortunately seldom encountered, may possess an inherent sensitivity to the drug which renders them more vulnerable to undesirable toxic effects. Because sulfapyridine is regarded as of relatively low toxicity, it does not follow that it can be safely administered without regard to the various toxic manifestations which may appear, sometimes insidiously but not infrequently with disturbing rapidity.

Cyanosis is a very common occurrence after the administration of sulfapyridine but, even though marked, is rather generally regarded as of minor significance and not per se indicating withdrawal of the drug. As might be expected, there is some uncertainty whether sulfapyridine cyanosis depends upon sulfhemoglobinemia or methemoglobinemia. Cyanosis is not infrequently a symptom in pneumonia and may be present before, and hence independent of, the administration of sulfapyridine. But since the cyanosis in pneumonia is directly related to the oxygen saturation of the arterial blood, any increase consequent upon the administration of sulfapyridine cannot always be regarded with entire equanimity and unconcern.

The recent observation by Doughty,⁷ corroborating the report by McGinty, Lewis and Holtzelaw,⁸ that the cyanosis and the usual concomitant headache, weakness, and nausea following the administration of sulfanilamide may be effectually relieved by the administration of 20 mg. of nicotinic acid three times daily, is of definite value and may furnish a clue to the mechanism of these complications.

As the oral administration of sulfapyridine is at times impractical or impossible, the recent report of Haviland and Blake⁹ is of interest. These investigators have found that a 0.15 per cent solution of sulfapyridine in normal (0.85 per cent) saline, or a 0.2 per cent solution in 5 per cent glucose solution, or in equal parts of normal saline and 5 per cent glucose, may be given intravenously without undesirable effects as long as the solutions are not allowed to cool below room temperature. The solutions are made by boiling and are allowed to cool spontaneously to room temperature. Such solutions have been given intravenously, subcutaneously, and within the arachnoid space and pleural cavity.

The main objection the authors cite is that large amounts (up to one or two liters) must be administered to procure adequate concentration. As in the presence of loss of fluid, salt, and glucose because of inadequate intake in comatose patients, or through vomiting, these substances may thus be replaced, the objection is of minor importance.

That sulfapyridine per se may produce a febrile reaction has been shown by many observers. It is important to differentiate this so-called "drug fever" from febrile exacerbations consequent upon the development of various complications. This may not always be easy for, though Graham, Warner, Dauphinee and Dickson¹⁰ report that drug fever is not accompanied by leucocytosis, this has not been the consistent experience of others.

In keeping with the observation that vomiting following the administration of sulfapyridine depends largely, if not entirely, upon central nervous system irritation, it has been recorded that various other central nervous system disturbances may occur. The more common of these are vertigo, headache, malaise, and mental depression. Occasionally, excitement of a degree severe enough to be classed as a psychosis occurs in approximately 4 per cent of cases. Fortunately these reactions are transient and disappear promptly on withdrawal of the drug.

Reference has already been made to the wide variation in the blood concentration and to the difficulty of maintaining the blood concentration at any set level with any degree of constancy. Many factors are probably concerned: variations in absorption, variations in the excretion rate, and variations in the degree and rapidity with which changes in the composition and structure of the drug occur after absorption, notably in the liver.

Just as bacteria entering the blood stream do not remain there as particulate entities continually traversing the circulatory paths but are rather rapidly removed through the interlocking activities of various mechanisms, so chemotherapeutic agents entering the blood stream are likewise subject to varying influences. Obviously, they are at once diluted by the blood volume; they may in part combine with its protein or other constituents, with their activities thereby decreased, if not entirely inhibited; and they are frequently altered by the detoxifying function of the liver.

It is known that compounds having a free para-amino group—of which sulfapyridine is one—undergo acetylation in the liver as a result of which the free amino group is blocked. Sulfapyridine may thus be rendered more or less inert after absorption. Fortunately, though this reaction occurs in the liver, evidence of tissue irritation as a by-product is exceedingly rare, so that toxic hepatitis and jaundice are very uncommon.

Like many other drugs sulfapyridine may produce a drug rash, the particular importance of which is that, as such patients appear to be definitely photosensitive, the severity of rash may be greatly intensified by exposure to light, particularly strong sunlight.

Since sulfapyridine in both its free and conjugated (acetylated) form is excreted almost entirely by the kidney, and since it may be present in the urine in concentrations much greater than its solubility can account for,^{11, 12} the occurrence of renal complications would not be unexpected. Thus a temporary de-

crease in the urica clearance, regarded as a toxic manifestation, has been reported by MacLeod,¹³ and hematuria, generally microscopic, though occasionally macroscopic, has been noted by many observers.

The incidence of hematuria is low—0.8 per cent in 2,300 cases, in one report. Since it shows evidence of renal irritation and damage, it indicates the necessity for frequent and periodic urinalyses during the course of sulfapyridine therapy. It is also well to maintain a high fluid intake to dilute the concentration of the drug in the kidney and lead to its rapid elimination. As sulfapyridine is more soluble in alkaline than in an acid solution, the proposal of Long and Wood¹⁴ that the urine be kept alkaline with sodium bicarbonate is worthy of note, even though it is purely empirical and as yet of unproved efficacy.

Of greater interest and more importance are the reports—relatively few but increasing in number—indicating the possibility of calculus formation as an aftermath of sulfapyridine therapy. Calculus formation in animals—the calculi being composed chiefly of acetylsulfapyridine—has been demonstrated experimentally by Toomey,¹⁵ Antopol and Robinson,¹⁶ and by Gross and associates.¹⁷⁻²⁰

It is not yet possible to determine accurately how frequently this complication occurs, but some evidence suggests that the incidence may be greater in children than in adults. That, rarely, grave and even fatal consequences may follow is shown by a fatality reported by Long and Wood,¹⁴ and one by Tsao, McCracken, Chen, Kuo, and Dale²² following renal blockage and uremia; in view of these fatalities the importance of routine urinalyses with attention to the presence of red blood cells and sulfapyridine crystals in the urinary sediment is obvious.

By far the most important and most dangerous complications of sulfapyridine therapy are those resulting from depression of the hematopoietic system and manifested by the occurrence of hemolytic anemia and agranulocytic neutropenia.

While both of these are important, the anemia—while not infrequent and tending to be progressive—is comparatively the less dangerous, since it is practically always controllable by transfusion and withdrawal of the drug. Although apparently essentially hemolytic in type, the anemia may vary in its manifestations, in some cases resembling a definite chloro-anemia; in other instances the reduction in the red blood cell count is disproportionate to the reduction in hemoglobin. Present opinion inclines to the belief that, where the need for continued administration is urgent, anemia of itself is not a mandatory indication for withdrawal of the drug unless the anemia reaches a degree dangerous per se, and particularly when it cannot be controlled by transfusion.

Agranulocytic neutropenia may take place early after the administration of only a small amount of sulfapyridine. Usually, once begun, it progresses rapidly. Its importance lies in the fact that marked leucopenia invites invasion of the tissues by opportunist bacteria, normally quiescent and particularly present in large numbers and varieties on mucous surfaces (mouth, rectum, vagina), leading to necrosing and extensive tissue damage and destruction.

It is well recognized that granulocytopenia in malignant degree is the aftermath and expression of profound depression of the bone marrow. But the

majority of reports suggest that this is most likely to occur when the dosage of sulfapyridine has been large and long continued. In common with other forms of grannlocytopenia dependent upon chemical intoxication, as contrasted to the form originally described by Schultz as agranulocytic angina which is now believed to be a filtrable virus disease, that following sulfapyridine therapy is more intense, and more likely to be dangerous in the presence of an individual sensitization or personal idiosyncrasy to the benzol ring. It is interesting to note that there appears to be no evidence that an individual can be sensitized to sulfapyridine itself.²³ Here, again, the importance of routine blood counts is evident, particularly because bone marrow damage may be manifest only after the cessation of sulfapyridine therapy.²⁴⁻²⁶

While this survey has been by no means comprehensive, it may serve to indicate that sulfapyridine therapy is still largely in the stage of clinical experimentation and, therefore, still in a state of flux.

It is unfortunate, in several respects, that the clinical use has far outstripped the careful and controlled laboratory study of sulfanilamide and its derivatives. It has been haphazard and empirical, to some extent based upon "wishful thinking," and has too often failed to appreciate that it is in large measure not clinical therapy, but clinical experimentation. What is the moral?

The moral, as I see it, is that if we are perforce engaged in mass clinical experimentation, we dare not evade the responsibility of so carrying on our investigations as to make them informative and ultimately of value. This means that our use of sulfapyridine and similar compounds that will inevitably follow it should be so safeguarded as to lessen the possibility of undesirable aftermaths, and so managed and controlled as to lead to a better understanding of its action, its capabilities, and the true indications for its use.

We, therefore, list the following desirable, and in some respects essential, adjuncts to the use of sulfapyridine in pneumonia:

1. The sputum should be typed in *every* case *before* the administration of sulfapyridine. Although this drug is not type specific in its action, knowledge of the type of pneumonia may lead to an evaluation of the place of sulfapyridine in treatment; it will give significant information in relation to prognosis; and it will indicate those cases in which the patient may best be served by combined serum and chemotherapy.

2. A blood count should be recorded *before* chemotherapy is begun, and the blood count should be frequently repeated as long as the drug is administered. It may profitably be continued for some days thereafter. It should be done *before* the institution of drug therapy to distinguish between antecedent anemia, leucopenia, or anemia arising from the disease per se and anemia due to drug toxicity.

The blood count should be *repeated* regularly during treatment because both anemia and granulocytopenia may appear insidiously and develop rapidly and progressively. Ravid and Chesner²⁷ have recently reported death from hemolytic anemia and nephrotic uremia on the third day of treatment after the administration of only 8 Gm. of sulfapyridine. As shown by post mortem, the uremia was apparently the aftermath of tubular blockage resulting from hemo-

siderosis and the presence of hemoglobin casts. There was also very probably some degeneration of the renal tubular epithelium reflecting a direct nephrotoxic action of the drug.

The blood should be observed *after* the cessation of chemotherapy because bone marrow damage may appear after the drug has been discontinued.

3. For reasons already discussed in some detail, routine and regularly repeated urinalyses should be a *sine qua non* of sulfapyridine therapy.

4. It is of great value whenever possible to take a blood culture *before* the institution of sulfapyridine therapy. First, because cultures taken *after* administration of the drug may be unreliable; second, because the blood culture, when positive, may confirm the sputum typing; third, because of the prognostic importance of bacteremia as an indication for energetic treatment, the combined use of serum and drug therapy, or perhaps for the use of sodium sulfapyridine intravenously. Bullowa and his associates,²⁸ in a series comprising 324 adults and 113 children, report that their lowest mortality rate in adults was observed in persons treated early (one to four days) with serum and sulfapyridine. The results in children were inconclusive.

5. While there is some uncertainty concerning the clinical importance of determinations of the blood concentration levels during the course of sulfapyridine therapy, whenever possible these should be done routinely at regular intervals to discover their ultimate clinical significance and value.

6. It is well to mix sulfapyridine therapy with a generous measure of the ingredient recommended by Whistler for use on the palette of the artist, namely, brains.

I am aware that in this somewhat discursive presentation, I have developed more problems and envisaged more difficulties than I have been able or, indeed, have attempted to solve. So much so that one might be tempted to echo the words of General Wolfe in one of his dispatches to Lord Pitt: "There is such a choice of difficulties that I find myself at a loss how to determine."

We may also remember the axiom of Oliver Wendell Holmes that, "Knowledge, like timber, should not be used until it is well seasoned."

If, in perspective, the vista seems one of doubt, of difficulty, even of confusion, we need not necessarily be unduly discouraged. Remember that the mills of science, like those of the gods, grind slowly—but they grind! And if, under the keen handling of the wise, the patient and the long enduring, their little grist grows even smaller as the chaff is winnowed away, that which is left is fine and pure and unalloyed, and from it comes strength and stimulus for the fight against disease.

I believe that we are only on the threshold of the successful chemotherapy of pneumonia. Sulfapyridine is but the forerunner of many sulfanilamide compounds to come. We have only to recall that it first became known as M & B 693, indicating that it was only one of many compounds synthesized in the laboratories of May and Baker at Dagenham, England, to realize the patient persistence of the investigator.

We have only begun the conquest of pneumonia, but we can now envision a conquest; heretofore we have had only a nebulous hope. We have taken the

first and the hardest step and may well expect that those to follow will be neither few nor laggard in their coming.

I hope this discussion will not have seemed entirely enveloped in uncertainty and disagreement. If this be so, let me recall the words of Herbert Spencer: "Mankind, in its progress, passes through three stages: the unanimity of the ignorant; the disagreement of the inquiring; and the unanimity of the wise."*

*ADDENDUM: Since this paper was written, two further communications have appeared concerning the mode of action of sulfanilamide.

Lockwood and Lynch²⁰ believe, from their investigations, that the bacteriostatic as well as they state, "very limited bactericidal action in vitro" of sulfanilamide are dependent upon the concentration of the drug and the concentration of "peptone" in the media. "Peptone," in this connection, they define as any product of protein digestion, whether artificially elaborated or arising through the operation of natural enzymatic processes.

They demonstrated experimentally in cultures that as little as 0.01 mg. of peptone per cubic centimeter definitely affects the bacterial population curve in that even these small traces had a definite inhibitory influence upon the action of sulfanilamide. They suggest as a tentative explanation of the action of sulfanilamide that the drug interferes with the ability of susceptible bacteria to utilize for food the protein-split products in serum, and that death then occurs through starvation and autolysis. The inhibitory effect of peptone, they suggest, arises from the fact that it supplies an excess of easily assimilable nitrogenous material which enables the bacteria to overcome the bacteriostatic action of sulfanilamide.

Another recent contribution to the mechanism of sulfanilamide action is that of Green²¹ based upon extensive experiments, mainly with *Br. abortus*. Green suggests that the action of sulfanilamide depends upon three factors:

(a) The rate of proliferation in the initial growth phase. If, in a fluid medium, the bacterial density reaches a certain level, which Green calls "critical," there is an accumulation in the medium of some antisulfanilamide factor sufficient to prevent further sulfanilamide effect. Possibly Green's "antisulfanilamide factor" may be the "peptone" of Lockwood and Lynch.

(b) The rate at which sulfanilamide reaches a concentration in the bacterial cell. The rate, he says, depends mainly upon the concentration of sulfanilamide in the medium, possibly in part on the nature of the bacterial envelope.

(c) The permeability of the capsule to the antisulfanilamide factor which is either released or formed during autolysis of the dead or dying bacterial cell and which diffuses into the surrounding medium. He suggests that the rate of such release and diffusion may be related to the chemical nature of the capsule and/or cell membrane peculiar to the bacterial species.

Green calls his antisulfanilamide factor the "P" or proliferation factor and suggests that it stimulates the same enzyme reaction in the bacterial cell which sulfanilamide inhibits, the reaction being probably fundamental in the metabolism of most, if not all, bacteria, but not in that of other living cells. This "P" factor is not species specific in source or action. He believes it probable that the sensitivity to sulfanilamide of any bacterial strain is conditioned by the rate at which the "P" factor is liberated by the autolyzing organism and that, under certain conditions, a balance may exist between sulfanilamide and the "P" factor when the organism, though still living, cannot reproduce.

This hypothesis may explain the clinical observation that infections apparently under control after the administration of sulfanilamide are exacerbated when the administration of the drug is stopped too soon.

Also of clinical importance is Green's observation that sulfanilamide-resistant strains may develop and that, under certain conditions, sulfanilamide may even act as a stimulant of bacterial growth because of the elaboration of the "P" factor.

CLINICAL AND EXPERIMENTAL

HYPERTENSION IN RELATION TO HEIGHT*

ITS VARIATION WITH BODY BUILD AND OBESITY

SAMUEL C. ROBINSON, M.D., CHICAGO, ILL.

NO RIGIDLY controlled statistical study on a large representative sample has ever established a correlation between height and blood pressure. This question is apparently settled in medical literature, since the majority of workers in the field have not been able to show any such relationship. Alvarez and Stanley,¹ most often quoted in this connection, say, "There is no correlation with height." Wunderlich,² in a study of German students, found "no correlation with stature." Reed and Love³ on a large group of United States Army Officers modified the statement somewhat and said the blood pressure was "but slightly, if at all, correlated with height." Stocks and Karn⁴ stressed the fact that even in early life, with other factors held constant, systolic pressure is not correlated with height.

Hunter⁵ found a slight increase in pressure with height, as did the Joint Committee on Mortality.⁶ This increase was greatest at an early age and least later in life. It must be remembered, however, that in many insurance studies height is obtained merely by questioning the prospective policy holder. Rueker,⁷ in a review of the literature, stated that at a very early age, before puberty, blood pressure is usually said to be correlated to length of the body, but Richey⁸ found that even this correlation disappeared when weight was held constant.

In contrast to these statistical studies the clinical impression among physicians is that there is a relation between hypertension and short stature. Fishberg,⁹ and other writers, characterized the hypertensive person as *short and stocky*. The fact that many men say "short and stocky" implies a height relation. We, therefore, find that the statistical evidence shows no correlation between stature and blood pressure, while clinicians are impressed that hypertension is found more commonly among short persons.

In our study of 10,883 persons we found a positive correlation of height to blood pressure in the different build and weight groups, a finding contrary to the general clinical impression.

*From the Department of Medicine, Woodlawn Hospital and Northwestern University.
A portion of this material was exhibited at the American Medical Association Meeting, St. Louis, 1939, and at the Inter-State Post-Graduate Assembly, Chicago, 1939.
The statistical and clerical work was done with the assistance of the Works Projects Administration. The tables and charts were prepared by personnel of the W.P.A. project 465-54-3-37-(3).

Received for publication, January 22, 1940.

STATISTICAL ANALYSIS

The distribution of 10,883 persons according to age, weight, sex, etc., details of examination, and careful estimation of blood pressure, build, and obesity are all presented in previous papers.^{10, 11} In general, the persons were examined in the nude. Weight was recorded on a beam scale; maximum height was obtained to a tenth of an inch; chest circumference was measured with a steel tape slightly above the nipple line during quiet breathing. Blood pressure was recorded with a mercury manometer on the left arm of the seated subject. The group was representative of the adult population between the ages of 20 and 70* years.

DISTRIBUTION OF HEIGHT

The average height of the men was 68.3 inches (68.2 inches when standardized to the United States population of 1934), with a standard range of 65 to 71 inches (Table I). This average is only a few tenths of an inch lower than that found by most other studies on the distribution of height. The Medico-Actuarial Investigation¹² found an average height of 68.5 inches. The average height of the women was 63.6 inches, with a standard range from 61 to 66 inches. Other studies on women show substantially the same average height. Dublin¹⁴ found 64.3 inches, while the Medico-Actuarial Mortality Investigation¹³ found 64.2 inches.

TABLE I
HEIGHT DISTRIBUTION OF 7,478 MEN AND 3,405 WOMEN

	MEN	WOMEN
Mean height	68.3 \pm 0.07	63.6 \pm 0.06
Median height	68.4	63.6
Mode height	68.6	63.6
Standard deviation	2.8	2.5
Standard range	65-71	61-66
Percentage under 60 inches	-1	7
Percentage 60-65 inches	11	66
Percentage 65-70 inches	61	26
Percentage 70 inches and over	27	-1

TABLE II
MEAN HEIGHT IN INCHES OF 7,478 MEN AND 3,405 WOMEN IN EACH DECADE

AGE	20-29	30-39	40-49	50-59	60-69	70 AND OVER
Men	68.7	68.3	68.0	67.8	67.5	67.3
Women	63.9	63.7	63.4	63.3	62.6	61.6

With an increase in age there is a slight decrease in the average height of a large group of persons (Table II). The greatest average height in young men was 68.7 inches; at 40 years of age it decreased to 68.0 inches, and at 70 years it was 67.3 inches. The group of women showed the same tendency. At 20 years of age the mean height was 63.9 inches; at 40 years it was 63.4 inches, and over

*For detailed description see: Robinson, S. C., and Bruce, M.: Range of Normal Blood Pressure, Arch. Int. Med. 61: 402, 1939.

70 years of age it was 61.6 inches. In both men and women the median and modal heights follow a similar age curve. This diminution of height represents a physiologic process of shrinking that most persons experience due to compression of the intervertebral disks, and also to postural changes.

But much more interesting than this decrease of the average stature of man with years is the tendency for the number of tall men and women to decrease after the third decade. Whereas at the age of 20, 5.7 per cent of the men are over 72 inches in height, after 60 years less than 1 per cent of the men are very tall. While 4.6 per cent of women are taller than 67 inches in the third decade, less than 1 per cent of women over 60 years of age are very tall. This is a very striking and statistically significant finding. We do not have an adequate explanation for this phenomenon, but shall discuss it later in terms of hypertension in the tall person. Increased mortality among tall persons is one of the explanations that must be seriously considered. On the other hand, the age incidence of short men and women increases as the group gets older. There are comparatively more short men in the older age groups than in the younger age groups.

TABLE III
INCIDENCE OF TALL MEN AND WOMEN AT VARIOUS AGES

AGE	20-29	30-39	40-49	50-59	60-69	70 AND OVER
Percentage of men under 63 inches	1.1	3.1	4.1	3.7	4.1	5.5
Percentage of men over 70 inches	19.5	14.5	13.1	11.1	8.8	2.8
Percentage of men over 72 inches	5.7	3.7	3.5	2.3	0.9	0
Percentage of women under 59 inches	1.0	2.6	4.4	5.0	6.6	20.0
Percentage of women over 65 inches	19.7	19.2	14.6	15.5	5.7	0
Percentage of women over 67 inches	4.6	3.5	2.3	2.6	0.9	0

RELATION OF HEIGHT TO BLOOD PRESSURE

If the body builds and weights of individuals are mixed, as they are in the chance distribution of any sample, height shows a slight correlation to blood pressure* (Table IV). The mean blood pressure of the men shows the short group to have slightly higher systolic and diastolic pressures than the tall groups (Fig 1). The short women have higher mean systolic and diastolic pressures than the tall women.

In order to study the possible effect of height on blood pressure, we divided the group into three height classifications: the very short, the medium, and the

*The correlation coefficients for the relation of height and blood pressure are as follows:

Men		Systolic Blood Pressure	Women	
r hs	$= -0.037 \pm 0.012$		r hs	$= -0.095 \pm 0.017$
η hs	$= 0.061$		η hs	$= 0.121$
ξ hs	$= 0.003 \pm 0.003$		ξ hs	$= 0.007 \pm 0.0003$
Men		Diastolic Blood Pressure	Women	
r hs	$= -0.002 \pm 0.012$		r hs	$= -0.030 \pm 0.017$
η hs	$= 0.051$		η hs	$= 0.072$
ξ hs	$= 0.001 \pm 0.0007$		ξ hs	$= 0.004 \pm 0.002$

Thus each correlation is a linear negative one and so small that without further careful investigation it would seem that height is not at all significant as a correlation to blood pressure.

Fig. 1.—The influence of height on blood pressure. In the total group, with various builds and weights indiscriminately mixed, the average blood pressure is slightly higher in short men and women than in tall.

very tall.* Because this division is used only for comparisons between the extremes, the arbitrary nature of the division makes little difference. If the divisions had been made either an inch higher or an inch lower, the results would have been essentially the same. It would be well, however, to establish a standard division in future statistical work.

TABLE V
MEAN SYSTOLIC PRESSURE IN VARIOUS HEIGHT CLASSIFICATIONS

HEIGHT	7,478 MEN	3,405 WOMEN
Short	121.9 \pm 0.90	117.6 \pm 0.82
Medium	120.0 \pm 0.49	115.1 \pm 0.70
Tall	119.7 \pm 0.56	114.1 \pm 1.01

TABLE VI
MEAN DIASTOLIC PRESSURE IN VARIOUS HEIGHT CLASSIFICATIONS

HEIGHT	7,478 MEN	3,405 WOMEN
Short	75.3 \pm 0.51	70.6 \pm 0.39
Medium	74.4 \pm 0.29	70.1 \pm 0.41
Tall	73.7 \pm 0.34	70.1 \pm 0.66

The blood pressure in these three height groups shows an interesting comparison (Table V). There is a 2.2 mm. difference in systolic pressure between short and tall men and 3.5 between short and tall women. These differences are statistically significant.† It is improbable that a purely chance distribution would cause such a difference.

The situation in diastolic pressure is similar to that in systolic pressure (Table VI). The difference of 1.6 mm. between the short and tall men is significant of an actual difference not due to chance errors in distribution.‡ The

*Because the differences between short and tall individuals were unexpectedly worthy of consideration, the two extreme height groups were augmented by a random selection from our files of 915 additional tall and short individuals.

Men

359 (plus 157) short	= under 66 inches
1,212 medium	= 66 to 70 inches
290 (plus 534) tall	= 71 inches and over

Women

734 (plus 208) short	= under 63 inches
767 medium	= 63 to 65 inches
296 (plus 16) tall	= 66 inches and over

These augmented groups were not used in Tables I and II, but were used only for the blood pressure comparison between short and tall persons so as not to affect the random character of the total sample. All discussions concerning age, height, and obesity (ponderal index) distributions are based on figures from the original sample of 7,478 men and 3,405 women. The discussion of blood pressures is based on a portion of this sample, 1,861 men and 1,797 women. The blood pressures of the original and the augmented groups are practically identical, which supports the genuine character of the results.

Men

Short	= 65 inches and under
Medium	= 66 to 70 inches
Tall	= 71 inches and over

Women

Short	= 62 inches and under
Medium	= 63 to 65 inches
Tall	= 66 inches and over

†The standard difference between the pressures of the short and tall men shows that to be least 2.5 mm. Because the actual differences are slightly greater than this standard difference, it is improbable that the difference is due to a pure chance distortion of the distribution.

‡The standard difference shows that to be significant the difference between the diastolic pressure of short and tall men must be at least 1.22 mm. For women the difference in diastolic pressure must be at least 1.52 mm.

difference of 0.5 mm. for women is not significant. Thus, in our total amalgam groups short men have slightly higher average systolic and diastolic pressures than tall men, and short women have slightly higher average systolic pressure than tall women.

The incidence of low and high pressures in short and tall men and women brings out more significantly the extent of these differences in the two extreme height groups. Twenty-five per cent of the short men have low systolic blood pressures, and 22 per cent of the tall men have systolic pressures under 110 mm. Forty-one per cent of short and tall women have systolic pressures under 110 mm. On the other hand, both men and women show a higher incidence of high pressures in the short groups than in the tall. Fourteen per cent of short men have high systolic pressures of 140 mm. and over, while only 9 per cent of tall men show these same high pressures. Twelve per cent of short women have a high systolic pressure, while only 5 per cent of tall women have pressures of 140 mm. and over.

Diastolic pressure shows a somewhat similar incidence variation. Again there is not much difference between the incidence of low pressures; 27 per cent of short men have diastolic pressures under 70 mm., while 29 per cent of tall men have these same low pressures. Fifty-one per cent of short women have low diastolic pressures, while 47 per cent of tall women have diastolic pressures under 70 mm. The incidence of high diastolic pressures shows significant differences between short and tall persons. Short men show an incidence of 8 per cent diastolic pressures of 90 mm. and over, while tall men show considerably fewer, only 5 per cent, high diastolic pressures. Short women show an incidence of 8 per cent and tall women 5 per cent high diastolic pressures.

It is thus seen that the mean as well as the distribution of low and high pressures both prove that the short men or women have more hypertension than their tall brothers or sisters. Offhand, without any further statistical breakdowns of the height groups studied, one might be led to believe, first, that stature per se exerted a strong influence on blood pressure and, second, that the short person was the one influenced more unfavorably. When the build and weight of each height group are held constant, it will be shown that the former statement is correct and the latter is false.

The data just presented were of the totals of each height group. To arrive at a true correlation of height to blood pressure it is necessary to separate our groups according to age, weight, build, and other factors that are known to be related to blood pressure.¹⁰⁻¹² If the short group has a larger number of persons that are fat and stocky, and if obesity and stockiness are related to hypertension, then the short group will show more hypertension but it will not necessarily be due to stature. To avoid such an error we must correct for these disturbing factors. This we do by holding the build and the weight factors constant in the different height groups.

RELATIONSHIP OF HEIGHT TO BLOOD PRESSURE IN SPECIFIC BUILD GROUPS

It is generally recognized by most anthropometrists that the gross morphology of mankind can be divided roughly into two contrasting build types,

the thin and the broad. The frame of the broad build person can be differentiated from the very narrow type of build by the chest/height ratio. This figure is obtained by dividing the chest circumference in inches by the height in inches. It is to be noted that the measure of weight is not used at all to arrive at this ratio. The simplicity of the index is its main asset and can be pictured easily by the rule-of-thumb statement that the chest circumference should be one-half the height, or a chest/height ratio of 0.50.

When the group is broken down into linear, intermediate, and lateral build classifications, slight differences are apparent (Table VII). Neither the linear nor the lateral build men show a statistically significant difference in mean or modal systolic or diastolic pressure between the short and tall classifications.

TABLE VII

COMPARISON OF MEAN AND MODAL PRESSURES OF 2,552 MEN AT VARIOUS HEIGHTS IN SPECIFIC BUILD GROUPS

PRESSURE			LINEAR BUILD (SLENDER)	INTERMEDIATE BUILD	LATERAL BUILD (BROAD)
Systolic	Short men	Mean	113.8	120.7	127.5
		Mode	107.5	112.7*	122.7*
	Medium men	Mean	113.7	120.5	125.3

	Tall women	Mean	109.1	118.1	134.0
		Mode	109.7	112.7*	122.0
Diastolic	Short women	Mean	66.8	69.7	75.9
		Mode	62.3	70.0	71.1
	Medium women	Mean	66.9	70.8	77.0
		Mode	63.6	71.4	70.4
	Tall women	Mean	66.4	72.6	84.0
		Mode	63.1	71.1	79.5

*Estimated mode.

The short linear women show the same mean and modal pressures that are found in the tall linear women. However, the intermediate build women show slightly higher pressures if they are tall than if they are short (Table VIII). This difference is most marked among the women of lateral build. But the maximum difference of about 8 mm. between short and tall in the lateral build is not statistically significant. Notice that the small differences which

do appear, while not statistically significant, are reversed from what was found in the total group. Tall persons show a greater hazard of hypertension than short persons in specific build groups.

Had we stopped at this point in our statistical survey of the relation of height to blood pressure even in the build breakdowns, we could not show any statistical correlation. Other studies, thus far, have relied solely upon the mean and mode, and hence, were unable to demonstrate any correlation.

More important than the mean or modal pressure is a study of the percentage distribution of low and high pressures in each build group of short and tall men and women. The tall linear men show fewer low pressures and more high pressures than short linear men (Table IX).

TABLE IX

COMPARISON OF THE INCIDENCE OF LOW AND HIGH SYSTOLIC PRESSURES IN 516 SHORT AND 824 TALL MEN

PRESSURE		LINEAR BUILD % (SLENDER)	INTERMEDIATE BUILD %	LATERAL BUILD % (BROAD)
Low	Short men	47*	26	16
	Tall men	30	19	13
High	Short men	3*	14	18
	Tall men	5	10	29

*Small distribution—less than 50 short linear men.

TABLE X

COMPARISON OF THE INCIDENCE OF LOW AND HIGH DIASTOLIC PRESSURES IN 516 SHORT AND 824 TALL MEN

PRESSURE		LINEAR BUILD % (SLENDER)	INTERMEDIATE BUILD %	LATERAL BUILD % (BROAD)
Low	Short men	47*	30	16
	Tall men	39	24	13
High	Short men	3*	6	16
	Tall men	1	6	23

*Small distribution—less than 50 short linear men.

The same relation is apparent in diastolic pressure (Table X). Although there is a smaller percentage of high pressure among tall linear men than among short linear men, the distribution in this group is small.

More important are the comparative incidences among lateral or broad build men. Tall men show a greater incidence of hypertension, both systolic and diastolic, than short men, and less low pressure. Whereas 16 per cent of short lateral men have low systolic and diastolic pressures, only 13 per cent of tall lateral men have these same low pressures. Only 18 per cent of short lateral men have systolic hypertension, whereas 29 per cent of tall lateral men have high systolic pressures. Sixteen per cent of short lateral men have diastolic hypertension compared with 23 per cent high pressures among tall lateral men.

The women show a similar relation within their height classifications (Table XI). Tall linear women show less low pressure and more high pressure, both systolic and diastolic, than short women. Among the lateral build women this is more marked. Only 12 per cent of tall lateral women have low systolic

PERCENT ACTUAL TO EXPECTED RATIO

pressures, while fully 26 per cent of short lateral women have these same low pressures, under 110 mm. Only 12 per cent of tall lateral women have low diastolic pressures, while 36 per cent of short lateral women have these same low pressures (Table XII).

TABLE XI

COMPARISON OF THE INCIDENCE OF LOW AND HIGH SYSTOLIC PRESSURES IN 942 SHORT AND 312 TALL WOMEN

PRESSURE		LINEAR BUILD %	INTERMEDIATE	LATERAL BUILD %
		(SLENDER)	BUILD %	(BROAD)
Low	Short women	53	44	26
	Tall women	52	32	12
High	Short women	3	9	29
	Tall women	0.6	8	30

TABLE XII

COMPARISON OF THE INCIDENCE OF LOW AND HIGH DIASTOLIC PRESSURES IN 942 SHORT AND 312 TALL WOMEN

PRESSURE		LINEAR BUILD %	INTERMEDIATE	LATERAL BUILD %
		(SLENDER)	BUILD %	(BROAD)
Low	Short women	60	51	36
	Tall women	62	35	12
High	Short women	2	6	18
	Tall women	2	8	24

The lateral build women show the same trend as men in respect to high pressure, although the difference in systolic pressure between short and tall women is not significant. However, 24 per cent of tall women have diastolic hypertension as compared with 18 per cent of short women.

It is thus seen that the study of the incidence of low and high pressures in different build groups shows a significant difference between tall and short persons. Generally speaking, the tall individual has a lower incidence of low pressure and a greater incidence of high pressure. This is most marked in the lateral build groups.

The actual to expected ratio* brings out comparative differences in a more illustrative manner and corrects for changes in distribution between the various heights. First, we shall discuss the linear or thin build. By segregating these persons in each height group and then comparing the actual to expected ratio of low and high systolic pressures, we find that the short linear or thin men have one and one-half times as many low systolic pressures, and nearly that many more low diastolic pressures as the tall thin men (Tables XIII and XIV). However, in the case of high systolic pressures the short thin men

*The per cent actual to expected ratio is very simply calculated and is of use in illustrating the relative effect of the extremes of one array upon the dispersion of another correlated array. The technique is used here to show the unusual influence of a broad build on blood pressure. For example, if in any random group of 100 males, 24 are of the linear type and 13 are of the lateral type, and if there is no correlation of build to blood pressure, then the same ratio of 24 linear types to 13 lateral types should hold true in any group of individuals whether they have low, medium, or high pressures. This, however, is not the case. Among a group of 100 hypertensive persons there are actually only 9 linear types to 23 lateral types. This gives a per cent actual to expected incidence of $9/24$, or a ratio of only 38 per cent of expected linear build hypertensive individuals as compared with $23/13$, or a ratio of 177 per cent of expected lateral build hypertensive individuals. Simply stated, this means that among hypertensive persons the lateral build predominates in a ratio of over 4 to 1. When this is done in each height group, the ratios can be compared as they correct for changes in the height-build distribution.

have only one-third the ratio shown for tall thin men (Figs. 2 and 3). The difference is reversed for diastolic pressure. In comparison of the short and tall men of the lateral or broad build groups we also find that the short men have more favorable pressures. There are about two and one-half times as many systolic and diastolic hypertensives among the tall men as among the short lateral men. The ratio for low pressures is also slightly in favor of the short men.

TABLE XIII

PER CENT ACTUAL TO EXPECTED INCIDENCE OF LOW AND HIGH SYSTOLIC PRESSURES AT VARIOUS HEIGHTS IN LINEAR AND LATERAL BUILD MEN AND WOMEN

	LOW PRESSURE*	HIGH PRESSURE		LOW PRESSURE	HIGH PRESSURE
Linear Build* (Slender)					
Short men	200	17	Short women	124	18
Medium Men	152	39	Medium women	126	37
Tall men	132	57	Tall women	128	12
Lateral Build (Broad)					
Short men	64	128	Short women	64	232
Medium men	50	167	Medium women	55	255
Tall men	50	300	Tall women	20	500

*For the purpose of this and other similar charts the terms used are defined as follows:
 Low pressure = Under 110 mm. systolic pressure and 70 mm. diastolic pressure
 High pressure = 140 mm. and over systolic pressure and 90 mm. and over diastolic pressure.
 Linear or slender build = Chest / height ratio under 0.50.
 Lateral or broad build = Chest / height ratio 0.59 and over.

ary and is used only to bring out the difference in the extremes his study finer subdivisions of chest/height ratio are usually type into the other. It does not imply that the intermediate of normal levels is discussed in another publication.

TABLE XIV

PERCENTAGE ACTUAL TO EXPECTED INCIDENCE OF LOW AND HIGH DIASTOLIC PRESSURES AT VARIOUS HEIGHTS IN LINEAR AND LATERAL BUILD MEN AND WOMEN

	LOW PRESSURE	HIGH PRESSURE		LOW PRESSURE	HIGH PRESSURE
Linear Build (Slender)					
Short men	183	33	Short women	118	24
Medium men	148	30	Medium women	123	30
Tall men	135	22	Tall women	132	34
Lateral Build (Broad)					
Short men	60	188	Short women	77	227
Medium men	58	150	Medium women	55	255
Tall men	50	450	Tall women	20	440

This same type of relationship holds for women in the lateral group but not for those in the linear group (Tables XIII and XIV). There is practically no difference in the actual to expected ratio of low and high pressures between the short thin women and the tall thin women. But there are twice as many systolic and diastolic hypertensive persons in the tall lateral as there are in short lateral women and less than one-third the low systolic and diastolic pressures.

In both linear and lateral build groups tall men have a far stronger tendency to develop hypertension and less tendency to develop low pressure

than their shorter brothers. The same holds true for women of the lateral build. This same tendency is reflected in the actual to expected ratio of low to high pressures within a specific build-height group. There will be a ratio of 12 low pressures to 1 high systolic pressure among short linear men, almost 4 low to 1 high among medium height linear men, and only a little more than 2 low to 1 high systolic pressure among tall linear men. This does not hold for diastolic pressure among linear men or for systolic or diastolic pressure among thin women. However, in the lateral build group, an unusual difference was found in both systolic and diastolic pressures among both men and women. Among lateral build persons the ratio is reversed. The lateral build person of any stature is always more susceptible to high pressure than to low pressure, but the tall lateral person carries the greatest hazard of all. Among short lateral men there will be only 2 high systolic pressures to 1 low systolic pressure. Medium height men show a ratio of more than 3 high systolic pressures to 1 low systolic pressure, while tall lateral men show a ratio of 6 high systolic pressures to 1 low systolic pressure. The women show a similar pattern. Short lateral women have almost 4 high systolic pressures to 1 low systolic pressure; medium height women show a ratio of almost 5 high systolic pressures to 1 low systolic pressure; and tall women show a ratio of 25 to 1. In other words, high pressure is far more common among tall lateral persons than among short lateral persons.

Diastolic pressure in lateral build shows the same trend. Among short lateral men there will be a ratio of 3 to 1, and among tall lateral men there will be a 5 to 1 chance of having a high diastolic pressure. Short lateral women show only a 3 to 1 ratio of high to low diastolic pressures, and tall lateral women show 22 high pressures to 1 low pressure. This extreme difference in the tall systolic and diastolic is erratic because of the small number of persons.

Thus it is apparent that for both men and women the tall lateral or broad person showed a greater predilection for systolic and diastolic hypertension than the short lateral person, and a lesser tendency to low pressure.

SUMMARY OF RELATION OF HEIGHT TO BLOOD PRESSURE IN SPECIFIC BUILD GROUPS

The summary of the relation of height to blood pressure in specific builds is brought out in the explanation of an apparent contradiction. We have shown that in our total group of 10,883 men and women the short persons had a higher mean pressure than the tall. On the other hand, after a study of the incidence of low and high pressures and the actual to expected ratio was completed in different build groups, we found that the tall individual was more susceptible to hypertension, especially if he was of the lateral build type. The increase in blood pressure of the tall person over the short *lateral* person is much greater than the increase of the mean pressure of the short person over the tall person in the total group. This is apparently a contradiction and must be explained. The explanation is to be found in the comparative distribution of build types in short and tall persons. In another paper it was shown that any lateral build person is more susceptible to hypertension than the linear type. Roughly, about three times as many lateral persons as linear persons are hypertensive. It can be seen that if there are more lateral builds among short men we would expect more

hypertension in the short group. This is precisely what we found. Twenty-four per cent of the short men are of the lateral build, while only 5 per cent of the tall men have a lateral build. The same is true for women. Thus in any sample of the population there will be far more short persons than tall lateral persons (Fig. 4). Although the tall lateral person is more susceptible to hypertension than the short lateral person, this increased susceptibility is more than offset by the greater number of short lateral persons in the total group. Hence, all short men together show a higher mean pressure than all tall men.

Fig. 4.—The distribution of linear and lateral build at different heights. Lateral or broad build is most frequently found in short men and women, and linear or thin build is most frequent among tall men and women. Blank sections indicate the intermediate build.

The clinical impression that the hypertensive individual is a short stocky man is therefore correct. The physician will see a far larger number of short stocky hypertensive persons and very few tall broad hypertensive ones merely because of the natural distribution of the lateral build in these two height groups. And yet the careful investigator must be aware that the tall broad individual is more susceptible to hypertension than any other person.

RELATION OF HEIGHT TO BLOOD PRESSURE IN SPECIFIC WEIGHT GROUPS

When the short, medium, and tall men and women are divided according to body weight groups, certain variations are important. The weight breakdown is done with the aid of the ponderal index, an index of relative obesity, the weight divided by the height. A low index (under 2.0) denotes a lightweight person, and a high index (2.5 and over) denotes an obese person. In a large sample of persons obesity is positively correlated to an increased blood pressure.

When the mean and modal pressures are compared in the various height-weight groups, no height difference in blood pressure is noticed in either lightweight or middleweight men (Table XV).

TABLE XV

COMPARISON OF MEAN AND MODAL PRESSURES OF 7,478 MEN AT VARIOUS HEIGHTS IN SPECIFIC PONDERAL INDEX GROUPS

PRESSURE			LIGHT- WEIGHT	MIDDLE- WEIGHT	HEAVY- WEIGHT
Systolic	Short men	Mean	117.6	121.5	128.5
		Mode	112.1	113.4	122.6
	Medium men	Mean	115.9	120.4	124.9
		Mode	110.5	114.4	118.0
	Tall men	Mean	117.5	118.3	123.9
		Mode	115.7	114.7	118.2
Diastolic	Short men	Mean	70.9	74.0	79.2
		Mode	71.2	70.7	78.9
	Medium men	Mean	70.5	73.6	78.5
		Mode	72.6	71.2	76.7
	Tall men	Mean	71.9	72.9	77.8
		Mode	70.7	72.0	73.3

TABLE XVI

COMPARISON OF MEAN AND MODAL PRESSURES OF 3,405 WOMEN AT VARIOUS HEIGHTS IN SPECIFIC PONDERAL INDEX GROUPS

PRESSURE			LIGHT- WEIGHT	MIDDLE- WEIGHT	HEAVY- WEIGHT
Systolic	Short women	Mean	111.8	119.8	127.6
		Mode	108.2	106.3	112.9
	Medium women	Mean	111.5	116.8	125.0
		Mode	108.2	112.1	110.9
	Tall women	Mean	109.8	115.6	121.2
		Mode	108.3	110.2	118.2
Diastolic	Short women	Mean	67.5	72.3	76.6
		Mode	63.3	71.1	73.3
	Medium women	Mean	67.6	71.5	75.7
		Mode	63.7	70.6	72.4
	Tall women	Mean	67.2	70.8	75.4
		Mode	67.5	70.5	70.3

TABLE XVII

COMPARISON OF INCIDENCE OF LOW AND HIGH SYSTOLIC PRESSURES IN 1,540 SHORT AND 1,078 TALL MEN (PONDERAL INDEX GROUPS)

PRESSURE		LIGHTWEIGHT PER CENT	MIDDLEWEIGHT PER CENT	HEAVYWEIGHT PER CENT
Low	Short men	35	23	16
	Tall men	24	24	16
High	Short men	9	13	22
	Tall men	3	7	14

TABLE XVIII

COMPARISON OF INCIDENCE OF LOW AND HIGH DIASTOLIC PRESSURES IN 1,540 SHORT AND 1,078 TALL MEN (PONDERAL INDEX GROUPS)

PRESSURE		LIGHTWEIGHT PER CENT	MIDDLEWEIGHT PER CENT	HEAVYWEIGHT PER CENT
Low	Short men	44	31	18
	Tall men	42	34	21
High	Short men	5	7	17
	Tall men	3	3	12

However, in the heavyweight men the tall group shows slightly lower systolic and diastolic pressures. At any height the men show higher pressures as they become heavier. However, the greatest increase is found in the short men where there is an increase of 10.9 mm. in mean pressure between lightweight and heavyweight men. Among tall men there is only a 6.4 mm. difference.

Lightweight, middleweight, and heavyweight women show the same systolic pressures at any height, but the short heavyweight women show a slightly greater diastolic pressure than the tall heavyweight women (Table XVI).

More informative than the mean and mode is a study of the distribution of low and high pressures among tall and short men in specific weight groups. Short men of any weight group show a greater incidence of high systolic and diastolic pressures than tall men (Tables XVII and XVIII).

A similar distribution is noted among women. The short women always show far more high systolic and diastolic pressures at any weight than tall women (Tables XIX and XX).

TABLE XIX

COMPARISON OF INCIDENCE OF LOW AND HIGH SYSTOLIC PRESSURES IN 1,383 SHORT AND 588 TALL WOMEN (PONDERAL INDEX GROUPS)

PRESSURE		LIGHTWEIGHT PER CENT	MIDDLEWEIGHT PER CENT	HEAVYWEIGHT PER CENT
Low	Short women	48	37	23
	Tall women	52	37	27
High	Short women	4	15	26
	Tall women	1	6	9

TABLE XX

COMPARISON OF INCIDENCE OF LOW AND HIGH DIASTOLIC PRESSURES IN 1,383 SHORT AND 588 TALL WOMEN (PONDERAL INDEX GROUPS)

PRESSURE		LIGHTWEIGHT PER CENT	MIDDLEWEIGHT PER CENT	HEAVYWEIGHT PER CENT
Low	Short women	59	40	30
	Tall women	56	47	28
High	Short women	3	7	15
	Tall women	1	5	10

The actual to expected ratio in the weight breakdown is not helpful in revealing the height differences in low and high pressures.

When short and tall persons are compared in specific weight groups, we find a complete reversal of the distribution of high pressures. In all three weight groups, light, middle, and heavy, short men and women have a higher incidence of high systolic and diastolic pressures than tall men and women. In the distribution of low pressures we found no difference between short and tall men and women in any weight group.

DISCUSSION

In our previous studies of 10,883 persons blood pressure was found to be correlated to both body build and obesity. However, since the literature is almost unanimous in stating that height does not affect blood pressure, no study of this

relation was contemplated. Almost accidentally, in a study of body build, it was discovered that the lateral person is most often of short stature. Since hypertension is most common in the lateral build it was reasoned, therefore, that height must show some effect on blood pressure. Accordingly, this study was made of the relation of height to blood pressure, and statistical breakdowns proved our reasoning to be true. The short person had higher mean and modal pressures and a higher incidence of high pressure than the tall person in the total group.

Since we have shown that the lateral build person of any height group is more susceptible to hypertension, it is obvious that the higher mean and modal pressure of the short group is a distortion due to a preponderance of lateral builds among short men. This could be corrected only by holding the build groups constant and then comparing the incidence of high and low pressures between short and tall persons.

When such a study was made of the blood pressure distribution within the various build-height groups, an entirely new and interesting height variation was discovered. The tall lateral person had a higher mean and modal pressure than the short lateral person, and a much greater incidence of hypertension. The tall lateral person had a smaller chance of having a low pressure than did the short lateral person. The actual to expected ratio further confirmed this striking finding. We, therefore, have an apparent contradiction in the influence of height on blood pressure. The true height difference is the greater hazard of hypertension carried by tall broad persons. The reversed finding in the total group showing the short persons to have more hypertension than the tall persons is due to the greater incidence of lateral build in the short group. Thus there is really no contradiction. The influence of build on hypertension is again strongly emphasized.

When the group was broken down into specific weight classifications, the short group was shown to have a higher incidence of hypertension than the tall group. This difference held true in all three weight groups. Height, therefore, influences blood pressure in two opposing ways. When the build is held constant, the tall person is more susceptible to hypertension. When the weight is held constant, the short person has the greater incidence of hypertension. How can these two divergent facts be reconciled?

The difference between tall and short in the various build groups is the true constitutional factor influencing blood pressure. This represents the morphologic and biochemical susceptibility to hypertension of the tall broad type, the exact nature of which requires further study. The pressure difference between tall and short men and women in the specific weight groups is dependent upon the greater incidence of lateral build in the short group. For, as we shall show in a subsequent study, obesity is linked to the lateral build. Therefore, we are really measuring to a great degree the lateral build factor when we study blood pressure in the short overweight person.

This finding, that hypertension is a greater hazard of the tall lateral person, suggests a comparison with Draper's¹⁵ contention that the women with hyperten-

sion "... are the tallest of all women. . . ." Draper does not make the same statement about men; nevertheless, our study surely confirms Draper's finding and probably holds for both men and women.

The analysis of the distribution of hypertension furnishes a partial explanation of the decrease in incidence of tall men in the older ages as pointed out earlier in this paper. The greater hazard of hypertension among the tall broad men should cause an increase in their mortality in the earlier age groups. Costanzo¹⁰ says that "as the age at death increased, body structure became more and more short shaped." However, the vast number of short hypertensive persons should distort the mortality records to show a much higher death rate among short men. The Medico-Actuarial Mortality Investigation¹⁷ confirms this supposition in the statement that "at the younger ages tall men have proved less desirable risks than short men. At the older ages the short men . . . have been slightly worse risks than tall men." Dublin¹⁴ makes the same statement for women but adds in another article¹⁸: "Extremes of stature [both short and tall] are decided handicaps."

The predilection of hypertension for lateral build has also made its mark on the mortality, as recorded by chest measurements. As Dublin¹⁹ states, "... The lower mortality is shown in the chest-girth groups below the mean." He implies further that in any height group the smallest chest has the lower mortality. Since hypertensive heart disease plays such a large part in crude mortality, it would

seem that much of the differential mortality of height groups can be explained on the basis of the hazard of hypertension among lateral build persons and the greater proportion of lateral build in the persons of short stature.

CONCLUSIONS

1. A gross anthropologic study of 2,552 men and 2,021 women shows for the first time in medical literature the positive correlation of height to blood pressure.

2. Blood pressure is shown in this study to be affected by height. A review of the literature shows that no study, thus far, has found the height difference as reported in this paper. An explanation for this failure is probably due to a lack of correct statistical delineation of build types and the exclusive reliance upon mean and modal pressures, instead of a study of the incidence of low and high pressure distribution and the actual to expected ratio.

3. The incidence of tall men and women decreased steadily with an increase in age. This is an unusual and striking phenomenon, and is probably due chiefly to a high mortality of tall persons in earlier age groups.

4. In a random group of mixed builds and weights short men and women will show higher mean and modal systolic and diastolic blood pressures than tall men and women. Short men and women showed a higher incidence of high pressures than tall men and women.

5. When the build groups are separated and held constant, a marked difference in blood pressure is noted between tall and short persons and is reversed to the height relationship mentioned above.

6. The tall lateral or broad individual is more susceptible to hypertension than the short lateral one and is less likely to have a low pressure.

7. Tall lateral or broad men show an actual to expected ratio of about two and one-half times as many systolic and diastolic hypertensives as short lateral men.

8. Tall lateral women show twice as many systolic and diastolic hypertensives as short lateral women.

9. Tall lateral women show less than one-third the low systolic and diastolic pressures as short lateral women.

10. Tall lateral men have a slightly smaller incidence of low pressure than short lateral men.

11. The actual to expected ratio shows that among linear or thin men the tall men have only one-half as many low systolic and diastolic pressures as the short men.

12. The actual to expected ratio shows no difference between short and tall linear or thin women of low and high pressures.

13. In a previous paper it was shown that the lateral or broad build individual in any height group carried the highest incidence of hypertension. In this paper it is shown that lateral build is most often found among short men and women.

14. This unequal distribution of lateral build in short and tall persons explains the discrepancy mentioned in conclusion number 5. Although the tall person carries a greater hazard of hypertension than any other individual, the

larger number of lateral builds among short persons causes the bulk of the hypertensive population to be found among short persons.

15. The short individual shows a higher incidence of hypertension than the tall one in any weight group.

16. There are, therefore, three influencing height factors in hypertension. First, there is the difference in blood pressure between tall and short persons in specific build groups. This is purely a height difference. Second, there is the difference in pressure between tall and short persons when weight is held constant. Third, there is the difference in pressure between short and tall persons in any total group in which build and weight are naturally mixed. The second and third height differences are dependent upon the build factor.

STUDIES ON EXPERIMENTAL LESIONS IN THE KIDNEYS OF RABBITS*

ARTHUR E. PARKS, M.D., AND G. SHANKS, M.D.
TORONTO, CANADA

THE purpose of this paper is to report the results of investigations on the production of experimental renal lesions in rabbits by homologous nephrotoxins and certain bacterial filtrates. The work of Shwartzman,^{1, 2} Gerber,³ and Apitz⁴ indicates that it is possible to damage rabbit kidneys by two or more injections of selected bacterial filtrates into the systemic circulation. Masugi⁵ showed that experimental lesions could be produced in the kidneys of rabbits by injection of duck anti-rabbit kidney serum. Smadel⁶⁻⁹ has reported similar results in rats by the use of rabbit anti-rat kidney serum. These lesions bore a striking similarity to those of human glomerulonephritis. To get a potent anti-kidney serum it was necessary to use two species of animals. Schwentker and Rivers¹⁰ showed that repeated injections of autolyzed rabbit brain into rabbits produced complement-fixing antibodies. This finding suggested that by autolyzing homologous protein, one could render it antigenic to the same species of animal. An attempt was made, therefore, to autolyze renal protein by tying off the renal artery of a rabbit's kidney and allowing it to degenerate in vivo. In the experiments to be reported rabbits were injected with emulsions of such degenerated kidney and their serum was used in an attempt to produce renal changes in other rabbits.

Other experiments were conducted in an attempt to damage renal proteins by a Shwartzman reaction.

EXPERIMENTS ON DEGENERATED RABBIT KIDNEY

Under ether anesthesia the left renal artery of a rabbit was ligated. Eighteen hours after ligation the rabbit was killed and both kidneys were removed aseptically. The left kidney was definitely swollen and discolored. The normal right kidney was perfused through the renal artery with sterile normal saline in order to remove the blood remaining in it at the time of death. No attempt was made to perfuse the degenerated kidney. Each kidney was then cut up aseptically with scissors and macerated in a mortar. Sterile emulsions of each were made by shaking up the macerated kidneys with 50 c.c. of sterile saline. Two rabbits then received seven intraperitoneal injections each of the two emulsions at daily intervals and were killed by bleeding to death. The blood from each rabbit was preserved carefully. On autopsy neither of these injected animals showed significant pathologic changes in the kidneys or other organs.

The precipitin titer of the blood of these two injected rabbits was examined by means of Wright's capillary-tube technique. It was found that precipitating

*From the Department of Medicine, University of Toronto, and the Department of Pathology, Toronto Western Hospital.

Received for publication, February 13, 1940.

antibodies to the dilutions of the ischemic kidney emulsion were present in significant amounts in the blood of the rabbit that had received that emulsion. The blood of the control rabbit that had received injections of normal kidney emulsion contained no precipitating antibodies.

Two other rabbits were subjected to intravenous injections of the precipitating rabbit serum. One received a single intravenous dose of 3 c.c. of serum and was killed nineteen hours later. Autopsy revealed no pathologic change in the kidneys or other organs. A second rabbit received six intravenous injections of the precipitating serum daily and was killed thirty-two hours after the last injection. On autopsy the kidneys showed no significant lesions. It was concluded from these experiments that, although the serum injected contained precipitating antibodies, there was no evidence of its being nephrotoxic in the sense of producing nephritis.

EXPERIMENTS WITH BACTERIAL FILTRATES

The bacterial filtrates used in these experiments were prepared from cultures of typhoid bacilli and hemolytic streptococci. Typhoid organisms were from a stock culture and the filtrates were prepared by the method of Shwartzman. These bacteria were grown on large surfaces of agar and washed off with normal salt solution. The washings were centrifuged and the supernatant fluid was passed through a Berkefeld filter. The resulting filtrate was used for the animal injections. In earlier experiments the streptococci used were obtained from an infected human knee joint. Those used in the last group of experiments were a group A hemolytic strain obtained through the kindness of Dr. Ronald Hare, of the Connaught Laboratories, University of Toronto. In both cases they were grown in broth and filtered through Berkefeld candles.

The technique of injection of the left renal artery was as follows: Under ether anesthesia a longitudinal lumbar incision was made. The lumbar abdominal muscles were split in gridiron fashion, and the artery and vein were exposed without perforating the peritoneum. Both vein and artery were freed of connective tissue, and a ligature was passed around the vein but not tied. The artery was elevated on a hook at the same time the vein was temporarily occluded by traction on the venous ligature. The artery was injected then by using a syringe and a bent needle. The volume of fluid injected was usually 2 c.c. A successful injection of the artery was evidenced by a distinct pallor of the kidney which could be seen through the peritoneum. The needle then was withdrawn and the hook occluding the artery was removed. Hemorrhage from the puncture in the arterial wall was controlled by a sponge soaked in saline at a temperature of about 44° C. The vein was kept occluded for five minutes in order to prevent the injected fluid from being washed out of the kidney immediately. The venous ligature was removed then and the circulation within the kidney allowed to re-establish itself. The kidney, which was blue and tense at the moment of release, would resume quickly its normal chocolate brown color and become much softer to the touch. The muscles of the loin were repaired and the wound was closed. Rabbits so treated showed no systemic ill effects.

EXPERIMENTAL RESULTS

(1) *Intra-Arterial Streptococcal Filtrate Alone.*—One rabbit received an injection of 1.5 c.c. of the first streptococcal filtrate in its left renal artery. No further injections were made, and the rabbit was killed twenty-nine hours later. Macroscopically the left kidney was slightly paler than the right, but microscopically no significant changes could be found.

(2) *Intra-Arterial Streptococcal Filtrate Followed by Single Intravenous Streptococcal Filtrate.*—The left renal artery of a rabbit was injected with 1.5 c.c. of the same streptococcal filtrate. In twenty-four hours it was given an intravenous injection of 1.5 c.c. of this streptococcal filtrate in the ear vein; the rabbit was killed four hours later. On autopsy the left kidney was paler than the right. Microscopically neither kidney showed any definite abnormality.

(3) *Intra-Arterial Typhoid Filtrate Followed by Single Intravenous Streptococcal Filtrate.*—The left renal artery of a rabbit was injected with 1.5 c.c. of the first typhoid filtrate. Twenty-four hours later an injection of 3 c.c. of the first streptococcal filtrate was made in the ear vein. The animal was killed five hours later. On autopsy the left kidney was pale and swollen while the right kidney was normal. The left kidney weighed 15.5 Gm., and the right kidney 11.5 Gm. Microscopically the left kidney showed little pronounced change in the glomeruli. Surrounding the capsule of a number of glomeruli was a zone of hyaline material which contained no nuclei; it stained pink with hematoxylin and eosin and red with Heidenhain's azocarmine aniline blue. There was disintegration of many proximal tubules with disappearance of nuclei, and similar damage was observed in some of the distal convoluted tubules. Many tubules down to the pelvis were seen to contain hyaline material similar to that described as surrounding some of the glomerular capsules. In this kidney there was damage to the tubules with exudation within as well as outside the nephron. No significant microscopic changes were observed in the right kidney. The liver showed fatty degeneration.

A second rabbit of this group received an injection of 2 c.c. of the second typhoid filtrate in its left renal artery. Twenty-four hours later it was given an intravenous injection of 2 c.c. of the first streptococcal filtrate in the ear vein. It died in about twenty-six hours. In the gross and microscopically both kidneys were normal.

(4) *Intra-Arterial Typhoid Filtrate Followed by Single Intravenous Typhoid Filtrate.*—A rabbit received 2 c.c. of the first typhoid filtrate in its left renal artery and 0.25 c.c. in the skin of the abdomen. At the end of twenty-four hours 3 c.c. of this typhoid filtrate were injected into the ear vein. The animal was killed five hours later. On autopsy the left kidney was slightly pale, and the skin showed no significant erythema. Microscopically some patchy areas of ischemic atrophy were seen in the left kidney. The right kidney was normal. No change was observed in either kidney that might not have been quite spontaneous in the rabbit.

A second rabbit of this group likewise was injected in its left renal artery with 2.5 c.c. of the second typhoid filtrate. At the same time an injection of 0.5 c.c. was made in the skin. Twenty-four hours later, at the time when the skin

Fig. 1—First rabbit of Experiment 3. Left kidney showing exudate about glomeruli and in some tubules.

Fig. 2—First rabbit of Experiment 3. Left kidney showing slightly damaged proximal tubules.

showed a slight erythema, an injection of 2 c.c. of the same second typhoid filtrate was made in the ear vein. The rabbit died three hours later. On autopsy the kidneys showed nothing of note.

Fig. 3.—First rabbit of Experiment 3. Left kidney showing loop tubules containing exudate.

Fig. 4.—First rabbit of Experiment 3. Untouched right kidney—undamaged.

(5) *Intra-Arterial Typhoid Filtrate Followed by Multiple Intravenous Streptococcal Filtrate Injections.*—A single rabbit was given 2 c.c. of a third typhoid filtrate in the left renal artery. Twenty-four hours later it received

an intravenous injection of 2 c.c. of the second streptococcal filtrate. These intravenous streptococcal filtrate injections were repeated once daily until 27 in all had been given. The rabbit was then killed. On autopsy the left kidney appeared pale and granular, and on section had a rather narrow cortex. The right kidney was normal. On microscopic section the left kidney showed marked focal fibrous atrophy. There were no glomerular lesions of note. The right kidney was normal microscopically. The lesions in the left kidney may have been due to the production of thromboses at the time of the arterial injection.

(6) *Intra-Arterial Typhoid Filtrate Followed by Multiple Intravenous Typhoid Filtrate Injections.*—A rabbit was given an injection of 2 c.c. of the third typhoid filtrate in its left renal artery. Twenty-four hours later it received 2 c.c. of the same filtrate in the ear vein, and thereafter daily intravenous injections of 2 c.c. of the same filtrate until 16 in all had been given. The rabbit was killed. On autopsy the left kidney was pale and had a large infarct. The right kidney was normal. Microscopically, apart from the infarct, there was much focal fibrous atrophy of the left kidney. The right kidney was normal.

(7) *Intra-Arterial Typhoid Followed by Multiple Intravenous Streptococcal Injections, Using Controls and Varying Time Intervals.*—Nine rabbits were used in the experiment subdivided into three groups of three. The first two groups were controls and the third the experimental group. The rabbits of the first group each received a single injection of 2 c.c. of the fourth typhoid filtrate in their left renal arteries. The rabbits of the second group each received daily intravenous injections of 2 c.c. of streptococcal filtrate but no antecedent arterial injections. The rabbits of the third, or experimental, group each received an injection of 2 c.c. of the typhoid filtrate in the left renal artery followed by daily intravenous injections of 2 c.c. of streptococcal filtrate. The first rabbit of each group was killed ten days after the initial injection, the second twenty days, and the third thirty days after that injection. The results were disappointing. No significant changes, gross or microscopic, were produced in the kidneys of any of the animals. Minor changes, such as focal fibrous atrophy, edema, and interstitial eosinophilic infiltration, were observed, but nothing that does not occur spontaneously in rabbits. It would appear that the treatment accorded these rabbits, control or experimental, was without effect in producing glomerular changes. Certainly nothing of the nature of glomerulonephritis was observed.

SUMMARY AND CONCLUSIONS

An attempt was made to produce pathologic changes in the kidneys of rabbits by intravenous injections of serum from rabbits that had been treated with intraperitoneal injections of degenerated rabbit kidney emulsion. An attempt was also made to damage rabbit kidney by bacterial filtrates. The results of these investigations were essentially negative. One interesting observation, from a serologic point of view, was the finding of precipitating antibodies in the serum of a rabbit that had been injected intraperitoneally with emulsions of degenerated rabbit kidney. Such precipitating antibodies could not be demonstrated in the blood of a rabbit that had received injections of a normal kidney emulsion. The renal lesions encountered in one rabbit described, while interest-

ing, could not be reproduced. The interpretation of the changes in this single rabbit must remain an open question. The possibility of an allergic reaction may be considered, but it could not be denied that a circulatory disturbance in handling the kidney might have been responsible.

DISTURBANCES IN THE BLOOD FOLLOWING EXPOSURE TO BENZOL*

LEONARD J. GOLDWATER, M.D., NEW YORK, N. Y.

INTRODUCTION

THE fact that benzol when taken into the human body may have deleterious effects upon the hematopoietic system has been known for about forty years.¹ With the exception of lead, there is probably no industrial poison better known to physicians than benzol. A rather extensive literature on the subject of benzol poisoning has accumulated, and most of the reports, especially the more recent ones, contain some mention of the blood picture. The most extensive review of the subject yet to appear is that of the British Industrial Health Research Board.² Another comprehensive review is that of Hamilton,³ published in 1931. The present status of knowledge concerning the blood picture in chronic benzol poisoning is well summed up in the following lines taken from the British report just mentioned: "While the most characteristic blood picture in benzol poisoning remains that described by the earlier authors, a leucopenia with neutropenia, thrombopenia and some anemia, it becomes increasingly evident that many cases present wide variations on this picture."

Most cases of benzol poisoning described in the literature have been fatal or at least of such severe degree that hospitalization has been necessary. Cases of this type are frequently complicated by hemorrhage, infection, or some other secondary factor. Whereas acute poisoning has been well differentiated from the chronic form, little distinction has been made between mild and severe forms of chronic poisoning. Relatively few observers have had an opportunity to study more than two or three isolated cases of chronic benzol poisoning, and not many of these have included a complete set of hematologic observations in their studies. Incomplete observations by a large number of physicians using different methods and terminologies and describing small numbers of cases must result in some confusion.

In the literature dealing with industrial poisoning, control studies are practically never mentioned. Benzol poisoning is no exception to this general rule. A careful observer would never consider publishing results of experimental poisoning in laboratory animals without having performed control experiments, even though "normal" values for the species of animal were supposed to be well known. In industrial poisoning the experimental animal is a human being. It seems entirely illogical to neglect establishing normals for the apparatus and methods in the hands of the particular individual who is making the study.

This paper presents the results of comprehensive hematologic studies on a large group of individuals who had been exposed to benzol. The significance of the results is enhanced by the inclusion of controls.

CASES STUDIED

The control group used in this investigation consisted of 81 male industrial workers employed in a factory where no occupational hazard could be demonstrated. These workers varied in age between 20 and 65 years. None gave a history of abnormal symptoms and none had any significant abnormal findings on physical examination. For all practical purposes the group could reasonably be considered to be a small but representative sample of the industrial population employed in a nonhazardous industry in New York City. A control series in the industry in which the benzol poisoning occurred was not possible, since no branch of that particular work is free of toxic materials.

TABLE I

TESTS PERFORMED AND NUMBER OF INDIVIDUALS SUBJECTED TO EACH TEST

BLOOD DETERMINATION	CONTROL	BENZOL	TOTAL
Hemoglobin	81	235	316
Erythrocytes	81	159*	240
Leucocytes	81	332*	413
Differential	81	112	193
Platelets	50	107	157
Reticulocytes	47	103	150
Bleeding time	52	105	157
Coagulation time	52	99	151
Sedimentation rate	59	104	163
Hematocrit	81	104	185
Mean corpuscle volume	75	103	178
Mean corpuscle hemoglobin	73	120	193
Mean corpuscle hemoglobin concentration	81	105	186
Fragility of red blood cells	68	92	160
Serum bilirubin	0	102	102

*Thirty-seven erythrocyte counts and 98 leucocyte counts were made by Dr. B. Mintz of the Division of Women in Industry, of the New York State Department of Labor. I made all other determinations.

The workers exposed to benzol (henceforth referred to as the benzol group) were employed in the rotogravure printing industry in New York City. A full description of this industry and its hazards has been given elsewhere. Suffice it to say here that every individual in the group had been exposed to concentrations of benzol fumes ranging from 11 to 1,060 p.p.m. for a period of at least six months, and in most instances for about three years.* In all, 33 rotogravure workers were examined. A complete set of hematologic observation was made in about 100 cases. The tests performed and the number of individuals subjected to each test are given in Table I. The age distribution of the control and benzol groups is shown in Table II. The differences between the two groups are not so great that they render comparison fallacious.

*The inks used in the particular type of rotogravure printing with which we are concerned contained chemicals other than benzol which might conceivably have produced toxic effects. Since benzol was the predominant solvent and since the effects were compatible with benzol intoxication, the other ingredients are not considered to be of great etiologic significance. The other solvents, all of which were used in relatively small amounts, were toluene, xylene, methyl ethyl ketone, petroleum naphtha, ethyl, butyl, and amyl acetate, and butyl and amyl alcohol.

Since there was no direct relationship between the duration of employment and the nature of the blood findings (Table III), this feature will not be discussed. All the individuals in the benzol group were actually working at the time they were examined. As a result of the blood studies, six were considered poisoned seriously enough to warrant hospitalization. Further studies on these patients have recently been reported.⁶ About 100 were referred to various physicians for observation and treatment. All but the six hospitalized persons were allowed to continue to work inasmuch as the use of benzol was discontinued shortly after this study was begun.

TABLE II
AGE DISTRIBUTION*

AGE GROUP	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
20-29 years	33	41.2	154	49.4
30-39 years	12	15.0	86	27.6
40-49 years	21	26.3	52	16.6
50-59 years	8	10.0	15	4.8
60-69 years	6	7.5	5	1.6
Total	80	100.0	312	100.0

*In a few cases the age was not ascertained.

TABLE III

CORRELATION OF LENGTH OF EXPOSURE AND BENZOL EFFECT

The differences in the various exposure groups are not statistically significant (chi square test)

BLOOD PICTURE	TIME OF EXPOSURE IN MONTHS							
	0-12 MO.		13-24 MO.		25-36 MO.		37-60 MO.	
	NUMBER	PER CENT	NUMBER	PER CENT	NUMBER	PER CENT	NUMBER	PER CENT
Normal	24	63.2	22	46.8	97	55.8	34	60.7
Abnormal	14	36.8	25	53.2	77	44.2	22	39.3
Total	38	100.0	47	100.0	174	100.0	56	100.0

METHODS

Erythrocyte and leucocyte counts were performed on capillary blood drawn from the finger tip. Bureau of Standards certified pipettes were used. For hemoglobin determinations the Newcomer method was used and readings were made on a photoelectric colorimeter.* This instrument was considered to offer many advantages, since on certain days as many as 30 or 40 hemoglobin determinations had to be made. Blood smears stained with Wright's stain were used for the differential counts, and a slight modification of Schilling's⁶ classification followed. In previous studies on smaller groups of subjects 200 cells were counted. Close agreement was found between the distribution of cells in the first and second hundreds so that in the present study, involving so many subjects, this refinement of technique was not observed.

Reticulocytes were vitally stained on slides previously prepared with a saturated alcoholic solution of brilliant cresyl blue. The number of reticulated cells observed while counting 1,000 erythrocytes was used as the basis for calculating the percentage of reticulocytes. Blood platelets were estimated from stained

*Kindly loaned by the Klett Colorimeter Company, New York.

smears of capillary blood drawn through a drop of 14 per cent magnesium sulfate solution, the smears being stained with Wright's stain. The number of thrombocytes observed while counting 1,000 erythrocytes was used as the basis for calculation.

The bleeding time was determined by Duke's method.⁷ Blood was drawn from the lobe of the ear by means of an automatic lancet adjusted to produce a uniform depth of incision. Coagulation time was measured on venous blood by the method of Lee and White.⁷ For calculating the sedimentation rate of the erythrocytes the method of Wintrobe and Landsberg⁸ was followed and the results were corrected for anemia. A mixture of ammonium and potassium oxalate was used as the anticoagulant. The hematocrit value was obtained in the same tube that was used for the sedimentation rate, and this value was used in calculating the mean corpuscular volume and the mean corpuscular hemoglobin concentration. These indices, as well as the mean corpuscular hemoglobin content, were obtained according to the methods of Wintrobe.⁹ To produce maximum packing of the cells, the hematocrit tubes were centrifuged at 3,600 r.p.m. for one hour.¹⁰ Fragility of the erythrocytes (resistance to hypotonic saline) was tested by the method of Sanford⁷ and serum bilirubin was determined as described by Ernst and Förster.¹⁰

Checking of Results.—In the controls as well as in the benzol group, where results of any test showed decided deviation from the normal, the test was repeated in many instances on a fresh specimen of blood. In a few cases repetition was not possible. Almost invariably the second test agreed closely with the first. Where there was disagreement, the figure nearer to normal was accepted.

NORMAL STANDARDS

In the present study it was not necessary to rely on the figures given in the literature for normal blood values, since a reasonably large control group comprised a part of this investigation. Most of the "normal" groups that have been reported have been made up of students, nurses, and similar types of individuals. Little has been written concerning the "normal" blood picture of industrial workers. There is no reason to believe that standards for workers in nonhazardous industries differ greatly from those of student groups. To support this view, Table IV has been prepared using Osgood's¹¹ figures for the purpose of comparison. The only significant difference seems to be in the hemoglobin values, there being no obvious reason for the discrepancy other than difference in method. Particular attention is called to the values for lymphocyte percentages. Most writers who have described blood findings in connection with industrial poisoning seem to have accepted the old idea that lymphocytes normally comprise 20 to 30 per cent of the leucocytes. As a result, practically every industrial poison is said to be associated with a relative lymphocytosis. If it is held that any value above 30 per cent of lymphocytes constitutes a lymphocytosis, one is quite certain to find a "lymphocytosis" in a large proportion

*In previous studies it had been observed that centrifugation at 3,600 r.p.m. for thirty minutes, as recommended by Wintrobe, did not always produce constant volume. It is possible that the modification used in the present study was responsible for the fact that the mean corpuscular volume range in the control series was lower than that reported by Wintrobe as normal.

globin were found only in those cases which had evidence of severe injury to the hematopoietic system. The results indicate that a low hemoglobin value is not a prominent part of the picture of chronic benzol exposure and in general is present only when the erythrocytes have fallen to a very low level. As will be pointed out later the hemoglobin values remained relatively high in relation to the erythrocytes. In other words, hyperchromia of the red corpuscles was the rule.

TABLE VI

DISTRIBUTION OF ERYTHROCYTE COUNTS IN CONTROL AND BENZOL GROUPS

ERYTHROCYTES (MILLIONS PER C.M.M.)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
1.5-1.99	0	0	1	0.6
2.0-2.49	0	0	1	0.6
2.5-2.99	0	0	3	1.9
3.0-3.49	0	0	3	1.9
3.5-3.99	0	0	22	13.9
4.0-4.49	2*	2.4	46	29.0
4.5-4.99	16	19.8	50	31.4
5.0-5.49	33	40.8	29	18.2
5.5-5.99	28	34.6	4	2.5
6.0-6.49	2	2.4	0	0
Total	81	100.0	159	100.0

*These two counts were 4.47 and 4.48 millions, respectively.

Erythrocytes.—Details of the erythrocyte counts are given in Table VI. Whereas but two individuals in the control group fell below 4.5 million (and these two but very slightly below), 76 workers, or 47.9 per cent, of those exposed to benzol whose red blood cells were counted had subnormal erythrocyte values. It is obvious, therefore, that a diminution in red corpuscles is a relatively frequent finding in chronic benzol exposure. The polycythemia described by certain observers,^{13, 14} in early benzol poisoning was not found in the present series. It is possible that if erythrocyte counts had been done on the entire group, some higher counts might have been encountered. On the other hand, since the individuals studied had been exposed from six to sixty months to concentration of 11 to 1,060 p.p.m., they may reasonably be said to represent all degrees of benzol effect, ranging from none at all to severe damage. It would seem that polycythemia, if it occurs in benzol exposure, should have appeared in at least a few members of the benzol group.

Qualitative changes in the erythrocytes, such as poikilocytosis, basophilic stippling and nucleated forms, were seen only in cases in which the degree of anemia was severe. All the severely anemic cases, however, did not exhibit these qualitative abnormalities. No effort was made to estimate the size of the red corpuscles from stained blood films, since it was felt that simple inspection was not entirely reliable and use of the Price-Jones technique was too time-consuming for a series as large as the present one. The average size of the erythrocyte (mean corpuscular volume) was calculated according to the method of Wintrobe. As will be shown later there was a definite tendency to macrocytosis in the benzol group.

Leucocytes.—As was stated in the introductory remarks, a leucopenia has always been considered one of the most characteristic features of benzol poison-

ing. If one considers only cases of an extreme degree of poisoning, this view is undoubtedly correct. If, however, reliance is placed on the finding of leucopenia to diagnose mild or early cases, serious error might result. In this connection Hamilton¹⁵ has stated that "if the physician depends on a leucopenia for the diagnosis and fails to make a count of the red cells, the patient may be fatally poisoned before he discovers that benzol poisoning has caused marrow aplasia." It can be seen in Table VII that only 14.5 per cent of the benzol group had less than 5,000 white blood cells and 69 per cent had more than 6,000 leucocytes. It might be argued that those patients having normal white cell counts were not really poisoned, but to sustain such a point of view one would have to contend that anemia, macrocytosis, and thrombocytopenia were no evidence of benzol poisoning.

TABLE VII

DISTRIBUTION OF LEUCOCYTE COUNTS IN CONTROL AND BENZOL GROUPS

LEUCOCYTES (PER C.M.M.)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
2,000-2,999	0	0	6	1.8
3,000-3,999	0	0	16	4.8
4,000-4,999	0	0	26	7.9
5,000-5,999	7	8.6	55	16.5
6,000-6,999	19	23.4	58	17.5
7,000-7,999	16	19.8	55	16.5
8,000-8,999	11	13.6	48	14.6
9,000-9,999	10	12.4	24	7.2
10,000-10,999	13	16.1	26	7.9
11,000-11,999	3	3.7	7	2.1
12,000-12,999	1	1.2	4	1.2
13,000-13,999	0	0	3	0.9
14,000-14,999	1	1.2	2	0.6
15,000-15,999	0	0	0	0
16,000-16,999	0	0	2	0.6
Total	81	100.0	332	100.0

It has occasionally been stated that leucocytosis is found in early benzol poisoning. The incidence of high white blood cell counts in the present series was not sufficiently frequent to support the view that leucocytosis is a characteristic feature in benzol exposure.

Lymphocytes.—Mention has already been made of the frequency with which relative lymphocytosis has been described in connection with industrial poisoning in general and benzol poisoning in particular. It is felt that the commonly accepted normal range of lymphocytes is far too low and that this misconception of what is normal has resulted in a certain amount of confusion. Inspection of Table VIII shows that lymphocyte percentages above 40 occurred in more than one-third of the control group, and that values above 50 per cent of lymphocytes were by no means rare. Further, only 12.4 per cent of the control group had between 20 and 30 per cent of lymphocytes. It has been pointed out in Table IV that the figures for range and average of this control group were very close to those given by Osgood^{11, 12} as his normals.

On comparing the benzol group with the control group (Table VIII) perhaps the most striking feature is that the incidence of lymphocyte values between 20 and 30 per cent, the traditional normal, was nearly three times as great in

TABLE VIII

DISTRIBUTION OF LYMPHOCYTE PERCENTAGES IN CONTROL AND BENZOL GROUPS

LYMPHOCYTES (PER CENT)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
10-19	2	2.4	10	8.9
20-29	10	12.4	41	36.6
30-39	40	49.5	41	36.6
40-49	23	28.3	15	13.4

Total	81	100.0	112	100.0

TABLE XI

DISTRIBUTION OF PLATELET COUNTS IN CONTROL AND BENZOL GROUPS

PLATELETS (PER C.MM.)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
14,000- 50,000	0	0	12	11.2
50,000- 99,000	0	0	23	21.5
100,000-149,000	9	18.0	31	28.9
150,000-199,000	11	22.0	20	18.7
200,000-249,000	20	40.0	12	11.2
250,000-299,000	8	16.0	6	5.6
300,000-380,000	2	4.0	3	2.8
Total	50	100.0	107	100.0

the benzol group as in the control group, whereas values above 40 per cent were twice as frequent in the controls. These findings can lead to but one conclusion, namely, that exposure to benzol produces, if anything, a relative *lymphopenia*. That this lymphopenia is absolute as well as relative is shown in Table IX. It will be pointed out later that in the present study relative lymphocytosis was not found even in those cases which showed evidence of severe damage to the hematopoietic system. It would seem that a frank relative lymphocytosis occurs with some frequency only in those cases of benzol poisoning which terminate fatally with a fully developed picture of aplastic anemia.

Differential Formula.—Except for the lymphocytes, no features in the differential formula require any extended comment. The neutropenia, so prominently featured in the literature, is based on the same questionable standards as the alleged lymphocytosis and so requires no further discussion. In performing the differential counts by Schilling's⁶ method, it was apparent that there was no significant shift of the polymorphonuclear cells either to the left or to the right. For this reason, there seemed to be no indication for doing Cooke or Arnetz counts.

As can be seen in Table X monocytosis and eosinophilia did not occur in the benzol group nor were unusual numbers of basophiles found. Myeloblasts or myelocytes were not seen in any of the blood smears that were examined.

Blood Platelets.—A reduction in the number of blood platelets was a frequent and significant finding in the group exposed to benzol. Table XI shows that 32.7 per cent of the benzol group had less than 100,000 platelets, while only 19.6 per cent had counts above 200,000. In the control group there were no counts under 100,000, and 60 per cent were above 200,000. The difference between the two groups was marked enough to indicate that a diminution in thrombocytes is an important part of the blood picture resulting from benzol exposure.

TABLE XII

DISTRIBUTION OF RETICULOCYTE PERCENTAGES IN CONTROL AND BENZOL GROUPS

RETICULOCYTES (PER CENT)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
0-0.5	16	34.1	40	38.8
0.6-1.0	28	59.5	38	36.9
1.1-2.0	3	6.4	22	21.4
More than 2.0	0	0	3*	2.9
Total	47	100.0	103	100.0

*The highest value was 2.4 per cent.

Reticulocytes.—As can be seen in Table XII the reticulocyte counts tended to be slightly higher in the benzol group than in the control group. In general, the higher values were found in those individuals who showed evidence of the most severe degree of damage to the hematopoietic system. No really significant increase in reticulocytes was encountered in the entire series.

Bleeding Time.—Table XIII shows some tendency toward prolongation of the bleeding time in the benzol group, but outspoken abnormality was rare. The two individuals whose bleeding time was longer than fifteen minutes had 46,000

and 30,000 blood platelets, respectively. These were by no means the lowest platelet counts found in the series. Of particular interest is the fact that although in 12 cases thrombocytes numbered less than 50,000, and in 35 cases were below 100,000, only two individuals had excessively long bleeding times, and in only three more was the bleeding time moderately prolonged. It is apparent that following benzol exposure it is possible for the platelets to reach a very low level without any change in the bleeding time.

TABLE XIII

DISTRIBUTION OF BLEEDING TIMES IN CONTROL AND BENZOL GROUPS

BLEEDING TIME (MINUTES)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
Less than 2	43	82.7	55	52.4
2-4	9	7.3	45	42.8
4.5-6	0	0	3	2.9
More than 6	0	0	2*	1.9
Total	52	100.0	105	100.0

*In these two cases the bleeding was controlled by local pressure after fifteen minutes

TABLE XIV

DISTRIBUTION OF COAGULATION TIMES IN CONTROL AND BENZOL GROUPS

COAGULATION TIME (MINUTES)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
Less than 9	10	19.2	29	29.3
9-12	34	65.5	53	53.5
13-16	7	13.4	13	13.1
More than 16	1	1.9	4	4.1
Total	52	100.0	99	100.0

Coagulation Time.—Inspection of Table XIV reveals that no significant difference in coagulation time between the control and the benzol groups was found to exist. In the two cases already mentioned as having prolonged bleeding time, retraction of the clotted blood was delayed and the clot remained friable

Erythrocyte Sedimentation Rate.—Included in the present studies for the sake of completeness is the erythrocyte sedimentation rate, which has been said to yield abnormal results in a great variety of diseased states. Table XV shows a very close agreement between the results in the control and benzol groups. It may be said that the sedimentation speed of the red corpuscles is probably of no significance in connection with benzol exposure.

TABLE XV

COMPARISON OF SEDIMENTATION RATES OF ERYTHROCYTES IN CONTROL AND BENZOL GROUPS

ERYTHROCYTE SEDI- MENTATION RATE (MM. PER HOUR)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
Less than 9	51	86.5	93	89.4
More than 9	8	13.5	11	10.6
Total	59	100.0	104	100.0

Hematocrit (Cell Volume).—It is not surprising that in the benzol group where anemia was a frequent finding, the hematocrit values should show

tendency to be lower than in the control group. Table XVI shows that in the benzol group nearly twice as many individuals were found with cell volumes less than 45 per cent as in the control group, and conversely, twice as many in the control group had values greater than 45 per cent. This difference is probably nothing more than a function of the anemia and has no specificity as far as benzol exposure is concerned.

TABLE XVI

DISTRIBUTION OF HEMATOCRIT VALUES IN CONTROL AND BENZOL GROUPS

HEMATOCRIT (CELL VOLUME %)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
Less than 40	1	1.2	16	15.4
40-44	31	38.4	59	56.7
45-49	47	58.0	27	26.0
50 or more	2	2.4	2	1.9
Total	81	100.0	104	100.0

Mean Corpuscular Volume (M.C.V.)—As was previously mentioned the mathematical method of measuring the average size of the erythrocytes was considered more suitable for the present study than methods depending on estimates or measurements of cell size in stained blood films. (M.C.V. = hematocrit $\times 10 \div$ red blood cells in millions.) Apparently this is the first time this method has been applied to a large group of individuals who have been subjected to exposure of the type described in this study. Since the test is simple and well standardized, comparison of subsequent studies with those reported here can reasonably be made.

TABLE XVII

DISTRIBUTION OF MEAN CORPUSCULAR VOLUME VALUES (AVERAGE SIZE OF ERYTHROCYTES) IN CONTROL AND BENZOL GROUPS

MEAN CORPUSCULAR VOLUME (μ)	CONTROL		BENZOL	
	NUMBER	PER CENT	NUMBER	PER CENT
70-74	7	9.3	1	0.9
75-79	9	12.0	2	1.9
80-84	19	25.4	9	8.8
85-89	20	26.7	19	18.5
90-94	13	17.3	24	23.2
95-99	3	4.0	15	14.6
100-104	4	5.3	16	15.5
105-109	0	0	8	7.8
110-114	0	0	7	6.9
115-119	0	0	2	1.9
Total	81	100.0	103	100.0

The normal range for mean corpuscular volume given by Wintrobe⁹ is from 80 to 94 μ . In the present study 69.4 per cent of the patients in the control group fall within this range, with 21.3 per cent below and 9.3 per cent above. In the benzol group 50.5 per cent fall within Wintrobe's normal range, 2.8 per cent are below and 46.7 per cent are above. The details are given in Table XVII. No matter how the figures are analyzed, no conclusion seems possible except that patients in the benzol group had larger erythrocytes than those in the control group; in other words, the anemia associated with benzol exposure is of the

macrocytic type. The fact that the technique followed for determining mean corpuscular volume was a slight modification of that described by Wintrobe⁹ does not invalidate the comparison between the control and benzol groups in this study.

Mean Corpuscular Hemoglobin (M.C.H.).—This method of expressing the average hemoglobin content of the erythrocytes is analogous to color index. It is the preferred method since it is not influenced by varying views as to what constitutes 100 per cent hemoglobin or 100 per cent red corpuscles. (M.C.H. = grams of hemoglobin per 1,000 c.c. of blood \div red blood cells in millions.)

According to Wintrobe,⁹ the upper limit of normal for M.C.H. is 32 μg . Table XVIII shows that no case in the control group exceeded this figure, whereas 30.9 per cent of the benzol group had abnormally high M.C.H. values. Further, in the low ranges, 24 to 29 μg , there were found 87.7 per cent of the controls and only 35.8 per cent of the benzol cases. The findings seem to indicate quite definitely that there is hyperchromia of the erythrocytes of individuals who have been exposed to benzol.

TABLE XVIII

DISTRIBUTION OF MEAN CORPUSCULAR HEMOGLOBIN VALUES (AVERAGE HEMOGLOBIN CONTENT OF ERYTHROCYTES) IN CONTROL AND BENZOL GROUPS

MEAN CORPUSCULAR HEMOGLOBIN (μg)	CONTROL		BENZOL

39	0	0	1	0.9
Total	81	100.0	105	100.0

Mean Corpuscular Hemoglobin Concentration (M.C.C.).—The purpose of performing the mean corpuscular hemoglobin concentration is to ascertain whether hyperchromia is merely a reflection of macrocytosis, or whether it is a result of actual overloading of cells with hemoglobin. (M.C.C. = grams of hemoglobin per 100 c.c. of blood \div hematocrit. The result is expressed in per cent.) Wintrobe⁹ gives 33 to 38 per cent as the normal range, this being slightly

higher than that of the control group in the present study. If one compares the benzol group with the controls (Table XIX), it is apparent that the great majority in each group fell between 30 and 35 per cent; 91.5 per cent of the controls and 88.6 per cent of the benzol group were in this range. Only one individual in the entire series had an M.C.C. value above Wintrobe's normal limit. Nevertheless, the trend in the benzol group is distinctly higher than that of the controls, and statistical analysis of the two groups (see Table XXII) indicates that there is a significant difference. This would suggest that the hyperchromia associated with benzol exposure is due not only to macrocytosis but also to increased concentration of pigment in the erythrocytes.

Fragility of the Erythrocytes.—The test for fragility of the erythrocytes was performed on 68 controls and 92 members of the benzol group. When the results in the two groups were compared, no significant difference was found. This being the case, the findings are not given in detail.

Serum Bilirubin.—Since the test for serum bilirubin was not performed in the control group, the normal values given by the authors of the method followed¹⁰ will have to serve for comparison. These observers state that a serum bilirubin value greater than 0.75 mg. per 100 c.c. of blood is abnormal. Table XX shows that 32.4 per cent of the workers in the benzol group exceeded this figure, with 10.8 per cent having more than 1.0 mg. per cent.

TABLE XX
DISTRIBUTION OF SERUM BILIRUBIN VALUES IN THE BENZOL GROUPS

SERUM BILIRUBIN (MG. PER CENT)	BENZOL	
	NUMBER	PER CENT
Less than 0.75	69	67.6
0.75-1.0	22	21.6
More than 1.0	11	10.8
Total	102	100.0

Patients Showing Severe Hematologic Abnormality.—In order that some comparison might be made between the present series and those cases which form the basis for most of the reports in the literature, a group of individuals showing severe hematopoietic damage has been selected for special consideration. The group was selected arbitrarily and consists of cases in which any one of the following conditions was present: 1. Erythrocytes of 3.0 million or less. 2. Leucocytes of 4,000 or less. 3. Platelets of 50,000 or less.

A composite picture of the more important findings in this group is given in Table XXI. Since these cases have been artificially selected, any extensive analysis of the blood pictures would have little meaning. Among other things, Table XXI reveals the following blood findings:

1. Every case but one showed some degree of leucopenia. In 3 cases (Nos. 9, 12, and 20) the leucopenia was not associated with significant diminution in erythrocytes or thrombocytes.
2. Fifteen of the 23 cases had subnormal red blood cell counts. In all but two of these the white blood cells and platelets were also distinctly subnormal.

3. Thrombocytopenia was present in 18 of the 23 cases. In two of these (Nos. 15 and 17) the erythrocytes and leucocytes were not significantly reduced.

4. The erythrocytes were abnormally large in 14 of the 22 cases in which size was determined.

5. Only one of the 22 cases with leucopenia had even a slight elevation of the lymphocyte percentage.

Actually the lymphocyte figures were lower in the severely involved group than in the control group. Values above 40 per cent occurred in 35.7 per cent of the latter as compared with 17.4 per cent of the former.

DISCUSSION

It would seem superfluous to indulge in any extended discussion of the foregoing findings. Points of interest to the industrial hygienist have received attention in another publication⁴ which deals with benzol poisoning as an industrial hazard.

Certain statistical analyses of the results were undertaken. These are summarized in Table XXII. The analyses consisted in comparing the controls with the benzol group to see whether significant differences existed. The data reveal that in all instances in which the results were tested the differences between the two groups can be considered significant. It should be borne in mind that in this comparison the entire benzol group, and not selected cases, was used.

SUMMARY AND CONCLUSIONS

1. Complete blood studies were performed on a relatively large group of individuals who had been exposed to concentrations of benzol vapor ranging from 11 to 1,060 p.p.m. for periods of from six to sixty months.

2. For comparison, similar studies were performed on a similar group of workers in a nonhazardous industry.

3. The abnormalities most frequently observed among the workers exposed to benzol were (a) anemia, (b) macrocytosis, and (c) thrombocytopenia.

4. Leucopenia was present in only a small percentage of the men who had been exposed to benzol.

5. Relative lymphocytosis was not found.

6. Comparison of the benzol group with the controls indicated that benzol exposure is likely to result in both relative and absolute lymphopenia.

7. Neutropenia was relatively rare; monocytosis, eosinophilia, and basophilia were not found in the benzol group.

8. Prolongation of the bleeding time following benzol exposure was rare in this study and did not parallel the reduction in thrombocytes.

9. Prolongation of the coagulation time was rare in the benzol group.

10. Relatively high hemoglobin values were a common finding in the benzol group. This abnormality was associated with macrocytosis as well as with overloading of red corpuscles with pigment.

11. The erythrocyte sedimentation rate is apparently not altered in benzol exposure.

12. The fragility of the erythrocytes does not seem to be significantly altered in benzol exposure but there seems to be a slight elevation of the serum bilirubin.

The studies covered in this paper were made while I was a member of the staff of the Division of Industrial Hygiene of the New York State Department of Labor. Through the courtesy of Dr. Leonard Greenburg, Executive Director of the Division of Industrial Hygiene, the data were made available for this report. Invaluable assistance in the statistical analyses was given by Dr. Morton Kramer, of the New York State Department of Health.

THE ARTERIAL CIRCULATION OF THE LOWER EXTREMITIES IN CHRONIC ARTHRITIS*

OTTO STEINBROCKER, M.D., AND SAUL S. SAMUELS, M.D., NEW YORK, N. Y.

A STUDY of the arterial circulation of the lower extremities in chronic arthritis was suggested by the repeated observation of vascular disturbances in patients attending the Arthritis Clinic. Such circulatory abnormalities, particularly vasomotor, have been mentioned occasionally in treatises on arthritis. Search of the literature reveals little attention devoted to the arterial circulation of the limbs in the rheumatic diseases. The need for investigation in this field was pointed out recently in the annual survey of publications on arthritis.¹

METHODS AND CRITERIA

The patients included in this series were suffering from arthritis and related conditions for which they were subjected to the routine physical and laboratory examinations of the clinic. They were then referred to the vascular department for study of the arterial circulation of their lower extremities. Every patient was examined by both of us. The diagnosis of arthritis or related condition was based on physical examination, laboratory data, such as total blood count, non-filament count, sedimentation rate, uric acid content of the blood, and roentgen examination. The diagnostic designations were rheumatoid arthritis, active or inactive; typical or atypical. Other classifications according to symptoms and signs were osteoarthritis, combined arthritis (osteoarthritis and rheumatoid), fibrositis, gout, and sciatic syndrome.

The criteria for the diagnosis of arterial disturbance were, in the order of importance: plantar ischemia, relative coldness of the feet, reduced oscillometric readings at the pedal and ankle levels, and diminished amplitude or absence of palpable arterial pulsation. Roentgen evidence of calcified arteries of the legs and feet was also taken into consideration. Plantar ischemia was sought after elevation and repeated flexion of the feet, according to the method described by one of us (S. S. S.). Rubor on lowering the extremities is not constant in incipient arterial disease but was noted when present. Relative coldness of the feet was estimated by a thermocouple and by palpation. Posterior tibial and dorsalis pedis pulses were palpated for their presence and amplitude. Pulse tracings of the feet and legs were made with a Tycoos recording oscillogram.

It is necessary to distinguish arteriosclerosis from arteriosclerosis obliterans. The former denotes structural changes in the walls of the arteries not, however, necessarily causing obstruction to arterial onflow. Calcification may be present to such a degree as to be visible in roentgenograms, but there may not be sufficient narrowing or blockage of the lumen of the arteries to cause diminished

*From the Arthritis and Peripheral Arterial Clinics, and the Medical and Surgical Services, Fourth Division, Bellevue Hospital, New York, Charles H. Nammack, M.D., Medical Director; Carl G. Burdick, M.D., Surgical Director.

Received for publication, March 4, 1940.

flow. However, when the element of obstruction is introduced by narrowing of the lumen or by actual blocking with a thrombus, the terminology as well as the physical conditions are changed, resulting in arteriosclerosis obliterans.

Unilateral arterial spasm occurs in varying degree in incipient organic arterial disease. As a rule, spasm merely accentuates existing changes produced by the organic lesion. In other words, it may intensify ischemia, it may increase coldness and may further diminish the amplitude of arterial pulsation. Any or all of these effects of spasm may be either abolished completely or modified by injection of novocain about the posterior tibial nerve. If ischemia, temperature, and pulse amplitude are affected by this injection, one must still consider the underlying condition an organic lesion because of its unilateral occurrence. Pure spasm in an isolated extremity is rare except in the case of direct external trauma to the large arteries of the limb.

For these reasons, the presence of plantar ischemia, coldness, and diminished or absent oscillometric pulsation either alone or in combination, with asymmetric distribution, has been considered definite evidence of arterial disease. The cause of the arterial obstruction has been ascribed in every such instance to arteriosclerosis obliterans because of the common prevalence of this disease. Thromboangiitis obliterans is excluded because of its characteristic clinical picture of incidence in young males with accompanying venous involvement. The absence of superficial migrating phlebitis in any of these cases lends further doubt to the diagnosis of thromboangiitis obliterans as the cause of arterial obstruction in any of the cases here reported.

DIFFERENTIAL POSTERIOR TIBIAL BLOCK

In those patients presenting evidence of arterial obstruction, posterior tibial block, as described by Scott and Morton,³ was performed. The procedure proved helpful in doubtful diagnostic situations. Anomalous response occurred in two patients, in one of whom the temperature rose without any accompanying increase in arterial pulsation; in the other an increased oscillometric reading was registered following the block, but the temperature rose only slightly. In addition to color and temperature observations, oscillometric pulse records were made before and after blocking.

FINDINGS

As Table I indicates, there were 47 patients with rheumatoid arthritis, 71 with osteoarthritis, nine with fibrositis, two with gout, two with gonorrheal arthritis, four with mixed arthritis, four with sciatica. The average age in the rheumatoid group was 44.4 years; in the osteoarthritis group, 51.3 years.

Plantar ischemia on elevation of the lower extremities, with or without brief flexion of the feet, was observed in 26 patients with rheumatoid arthritis, and in 22 patients with osteoarthritis. In a few patients with rheumatoid arthritis accompanied by vasomotor disturbances some plantar blanching was noticed in the normal position.

Palpable coldness, or lowered skin temperature, was noted in 26 rheumatoid patients and in 22 osteoarthritic patients. These observations confirm previous reports of the surface temperature changes in these diseases. The tem-

perature abnormalities were determined by thermocouple readings. It was found that gross estimation of temperature differences in the two extremities by the fingers of a trained observer were as reliable as instrumental readings in about 80 per cent of the cases.

TABLE I

TYPE OF ARTHRITIS	RHEU- MATOID	OSTEOAR- THRITIS	FIBRO- SITIS	GOUT	G.C.	MIXED	SCI- ATICA

Spasm	28	23	0	1	0	3	0
Negative	(59.5%)	(33%)					
Arteriosclerosis obliterans %	6.3%	2.8%	8	0	2	1	3
Total vascular disturbances	65.9%	35.2%					

Oscillometric readings were diminished in 22 patients with rheumatoid arthritis and in 18 with osteoarthritis. The amplitude of individual oscillations was important in determining any abnormal variation. Differences in readings at corresponding levels of both extremities, as illustrated in Figs. 1 and 2, were considered of great diagnostic importance.

Pulsations of one or more arteries were absent in nine patients with rheumatoid arthritis and in eight with osteoarthritis. Pulsations of the dorsalis pedis and of the posterior tibial arteries were studied. While an effort to determine the presence and the force of these pulses was made, this information was considered to have little, if any, diagnostic value in incipient arterial disease. Color changes on lowering the extremities were found in a small number of patients. Cyanosis of the feet was observed in ten patients with rheumatoid arthritis and in 11 with osteoarthritis. Rubor was noted in 15 patients with rheumatoid arthritis and in five with osteoarthritis.

Symptoms indicating intermittent claudication, despite the high incidence of circulatory abnormality, were elicited in only two patients with rheumatoid arthritis and in one with osteoarthritis.

Paresthesias of the lower extremities were described by five patients with rheumatoid arthritis and five with osteoarthritis. These symptoms are interesting and present a diagnostic problem in arthritis with arterial disturbance because of the difficulty of relegating them to either a circulatory or an arthritic basis.

In accordance with the above findings, as indicated in Table I, 28 patients with rheumatoid arthritis were considered as presenting evidence of vasospastic arterial disturbance; 23 patients with osteoarthritis showed signs of a similar condition. Three patients with rheumatoid arthritis gave conclusive evidence of arteriosclerosis obliterans, while two patients with osteoarthritis

appeared in the same category. When the findings were suggestive, but not definitely indicative of occlusion, the case was placed in the vasospastic group. There were eight such cases.

In a group of nine patients with fibrositis one showed signs of arteriosclerosis obliterans. In none of the others was there demonstrable evidence of arteriospasm. Of four patients with combined arthritis three had varying degrees of arteriospasm. One of four patients with sciatica showed arteriosclerosis obliterans; in three there were no vascular abnormalities. Of two patients with gout there were signs of arteriosclerosis obliterans in one and of arteriospasm in the other. Two patients with gonorrheal arthritis showed no circulatory disturbances.

Fig. 1.

Fig. 1.—Reduced and unequal pedal pulses in arthritis. Each tracing shows both pedal pulses in the same patient.

Fig. 2.

Fig. 2.—Reduced and unequal tibial pulses in arthritis. Each tracing shows both tibial pulses in the same patient.

In our survey of 139 patients with rheumatic disease, therefore, seven presented signs of arteriosclerosis obliterans. Insufficient or no evidence for diagnosis of arterial disturbance occurred in 16 of 47 patients with rheumatoid arthritis, and in 47 of 71 patients with osteoarthritis.

In the series as a whole, of 47 patients with rheumatoid arthritis, 28, or 59.5 per cent, showed signs and symptoms of vasospastic arterial disturbance. Of 71 patients with osteoarthritis, 23, or 32.3 per cent, gave evidence of a similar condition. In the rheumatoid group three, or 6.3 per cent, gave indications of arteriosclerosis obliterans, whereas two, or 2.8 per cent, with osteoarthritis, presented a similar complication.

Within the rheumatoid group of 47 patients, then, 31, or 65.9 per cent, gave clinical evidence of abnormality in the arterial circulation of the lower extremities, while of 71 patients with osteoarthritis 25, or 35.2 per cent, presented such findings. Several patients in other classifications indicated in Table I showed signs of arterial disturbances, but these groups were so small that the individual cases, although suggestive, will not be considered further in this discussion. One patient with rheumatoid disease and another with osteoarthritis suffered from gangrene of an extremity. In each of these, however diabetes mellitus was a pronounced complicating factor.

RELATION OF PERIPHERAL ARTERIAL DISTURBANCES TO LOCATION OF ARTHRITIS

A natural question arising in the course of this investigation was the possibility of a relationship between circulatory signs and arthritic involvement in the same extremity. As shown in Table II, a limited local reaction in isolated extremities did appear in a small number of patients and suggested as one possible source of vasomotor symptoms a local reflex angiospasm perhaps as a reaction to the nearby painful joint. While this study was confined to recording the arterial signs in the lower extremities, striking vasomotor symptoms in the upper limbs of these patients were frequently seen.

The influence of rheumatoid disease upon the location of vasomotor manifestations is indicated in Table II. Of 23 patients with active rheumatoid arthritis presenting vasomotor disturbances of the lower extremities, 17 had arthritic symptoms that involved all extremities, five showed limitation of joint trouble to the upper extremities, and only one to the knees and feet. In eight persons with inactive but symptomatic rheumatoid disease and associated circulatory signs in the lower extremities, six showed generalized joint involvement and discomfort; one presented arthritic symptoms restricted to the knees and feet, and one had involvement of the upper extremities only. These observations indicate that the location of peripheral vasospasm in many of the patients is unrelated to the site of rheumatoid activity.

Of 71 patients with osteoarthritis, as listed in Table II, 25 showed arterial disturbances of the lower extremities. Only ten of this group presented arthritic complaints limited to the joints of the lower extremities.

The higher, almost twofold, incidence of vasomotor symptoms found in rheumatoid disease as compared with osteoarthritis raises the question as to whether varied causative factors account for the difference. Close analysis

reveals that circulatory symptoms are not as prevalent in rheumatoid arthritis when the infectious process has subsided. Table II shows that the frequency of arteriospastic signs was highest in active rheumatoid arthritis (23 of 30 patients, or 77 per cent), next highest among those with inactive rheumatoid arthritis (8 of 17 patients, or 47 per cent), and least (25 of 71 patients, or 35.2 per cent) in osteoarthritis.

It is tempting to attribute the high incidence of peripheral arterial symptoms in active rheumatoid disease to the irritative effect of the underlying systemic infection. Such an assumption, however, could not clearly explain similar circulatory symptoms in apparently inactive rheumatoid arthritis and certainly does not account for vasospastic complaints in osteoarthritis which is generally considered to have a degenerative rather than an infectious basis.

It is readily discerned that the one clinical feature all of the three groups of arthritis present in common is symptomatic, painful articular disease. After thorough consideration of these facts one, therefore, must deduce that in these joint conditions some close, dynamic relationship may exist between painful, arthritic symptoms and the peripheral vasomotor imbalance with which they are frequently associated. Such a relationship appears most commonly, it is true, in the presence of active rheumatoid disease in which it is probable that systemic infection alone often may produce the circulatory disturbances by a local, toxic neurovascular reaction or, more likely, by central stimulation of the vegetative nervous system. It is further possible that systemic toxins in active, rheumatoid arthritis may supplement and augment the reflex mechanism initiating arterial disturbances, presumably as in quiescent rheumatoid infection and in osteoarthritis. This does not include the majority of patients with symptomatic osteoarthritis who do not present vasomotor disturbances.

ARTHRITIS IN PATIENTS WITH VASCULAR DISEASE

As a control of the vascular study in arthritis, a group of patients with evidence of long-standing arterial disease attending the vascular clinic were studied for history, complaints, signs, and roentgen evidence of arthritis. According to Table III, of 86 individuals in this series under treatment for frank arterial disease, 58, or 67.6 per cent, gave no information or signs of rheumatic involvement at any time. Twenty-eight patients, or 32 per cent, yielded positive histories, physical signs, or roentgen evidence of rheumatic or arthritic involvement in some form.

THERAPY IN ARTERIAL DISTURBANCES IN ARTHRITIS

A variety of medical^{4, 5} and surgical^{6, 7} measures have been suggested to improve the peripheral circulation in arthritis. Although this report embraces an essentially diagnostic investigation, mention of some therapeutic experiences may not be irrelevant. A limited group of patients with arthritis showing vasospastic or occlusive disturbances were subjected to intravenous hypertonic saline therapy. Of 12 patients treated from three to eighteen months, seven showed marked improvement in symptoms, particularly in relief of discomfort in the lower extremities and in their ability to walk longer distances without the usual pain. The known angiospastic influence of tobacco warrants restriction of smoking in arthritis with severe vasomotor symptoms, together with other special care recommended for those patients with signs of arterial occlusion.⁸ The accepted value of alcohol in circulatory disturbances makes it a worthy addition to therapy in arthritis⁹ when vasospastic complaints are present.

SUMMARY AND CONCLUSIONS

1. In a clinical investigation of rheumatoid arthritis, 65.9 per cent of the patients showed abnormalities, usually vasomotor disturbances, of the arterial circulation of the lower extremities; in osteoarthritis 35.2 per cent of the cases presented similar findings. Three rheumatoid patients, or 6.3 per cent, had simultaneous arteriosclerotic occlusive disease; two with osteoarthritis, or 2.8 per cent, presented evidence of arteriosclerosis obliterans.

2. Study of those patients with arthritis presenting arterial abnormalities showed no direct, consistent relationship between the location of the vascular signs and the site of the arthritic process. The evidence suggests that the vasomotor disturbances in chronic rheumatoid arthritis and related conditions may be attributed to some systemic reaction probably acting through the sympathetic nervous system, although in some cases a local irritative reflex vasospastic mechanism in the painful arthritic extremity cannot be ruled out.

3. In a control group of 86 patients with advanced organic arterial disease, 28, or 32 per cent, offered a history, physical signs, or roentgen changes of rheumatic or arthritic involvement at some time. These findings approximate the incidence of such ailments in similar age groups of individuals without arterial disturbances and contribute clinical evidence that pronounced arterial disease alone does not usually produce arthritic signs and symptoms.

EPINEPHRINE OUTPUT FROM THE ADRENAL GLANDS IN EXPERIMENTAL HYPERTHYROIDISM*

J. M. ROGOFF, M.D., Sc.D., PITTSBURGH, PA., AND
RUTH CORTELL, Ph.D., CHICAGO, ILL.

IT IS often assumed that changes in irritability of the sympathetic nervous system that occur in hyperthyroidism are related to a corresponding increase in the rate of liberation of epinephrine from the adrenal glands. The investigation reported here was undertaken to obtain quantitative information on this question.

A significant role in the etiology and pathology of hyperthyroidism and of a number of other diseases, notably diabetes mellitus and arterial hypertension, is commonly attributed to the adrenal medulla. This is based chiefly on pharmacodynamic, sometimes toxic, reactions that are obtained on administration of epinephrine in pharmacologic doses. Support of quantitative measurements of the epinephrine output from the adrenals, under appropriate experimental conditions, is lacking.

Eppinger, Falta, and Rudinger¹ postulated a mutual stimulating interrelationship between the thyroid gland and the adrenal medulla. They suggested the probability that, in hyperthyroidism, the excess thyroid secretion may stimulate secretion of epinephrine from the adrenals, which in turn is responsible for increased irritability of the sympathetic nervous system. Such an interrelationship between the thyroid and adrenal glands seems unlikely, for, if it existed, a vicious cycle of mutually induced hypersecretion from both these glands might lead to accumulation of relatively large amounts of epinephrine and of thyroid hormone in the circulation.

We do not assume that experimentally created conditions are identical with similar conditions that occur clinically. Nevertheless, since certain of the pathologic manifestations often are attributed to an associated increase in the output of epinephrine from the adrenals, it seemed desirable to perform quantitative experiments for determination of the rate of liberation of epinephrine into the circulation in dogs subjected to prolonged thyroid feeding. These experiments are part of an investigation on possible functional interrelationships between the adrenals and the thyro-parathyroid apparatus. Experiments related to the parathyroid will be reported in another paper.

Six adult dogs, three males and three females, received desiccated thyroid (Armour's), represented to contain 0.2 per cent iodine, for periods ranging from three to twelve and a half weeks. The dosage of thyroid ranged from

Received for publication, March 5, 1940.

0.5 Gm. to 1.3 Gm. per kilogram of body weight, administered daily together with the regular food. The routine diet consisted of a mixture of boiled beef lung, white bread, and bone meal.

Water intake and urine output were measured daily. Pulse rate and body weight were recorded at frequent intervals, and in four of the animals observations of the rectal temperature were made from time to time. In three dogs, one of which served as a control, observations of the basal metabolic rate were made as an indication of the degree of experimental hyperthyroidism that was induced.

Kunde² has demonstrated that thyroid feeding, in doses and for periods comparable with those of our experiments, induces a hyperthyroid condition in dogs. Our determinations of the basal metabolic rate were made essentially according to the method employed by Kunde. The dogs, previously trained to lie quietly, were fasted for eighteen to twenty hours. Each observation was preceded by a preliminary "rest" period. A specially devised mask was fitted to the animal and was connected with a Benedict-Roth closed circuit apparatus for determination of oxygen consumption. At the conclusion of each observation the rectal temperature and pulse rate were recorded. Observations of the basal metabolic rate were made approximately four times weekly throughout the course of the experiment.

After a sufficient number of observations were made to determine a base line for each factor, administration of thyroid was begun. At the end of the period of thyroid feeding the animals were sacrificed for determination of the rate of liberation of epinephrine from the adrenals. The epinephrine output was measured by the method of Stewart and Rogoff, obtaining adrenal vein blood at a known rate of flow, via the "cava pocket," and determining the epinephrine concentration in the blood by its action on rabbits' intestine segments. Ether anesthesia was employed for the operative procedure.

All the epinephrine assays were performed by the same individual (R. C.). Epinephrine output was determined in eleven normal dogs for comparison with the experimental animals, under the same laboratory conditions. These are included in Table I. The results obtained compare very well with those in the large series of animals reported by Stewart and Rogoff.³

Table II illustrates the results obtained in the experiments on thyroid-fed dogs. Definite loss in body weight was observed in all animals, the largest percentage loss having occurred in the two dogs (Nos. 19, 25) that were subjected to thyroid feeding for the longest periods. For convenience, the figures given in the table for heart rate, rectal temperature, and basal metabolic rate are the averages for the control period and for the period of thyroid feeding. It may appear from the averages that differences between the figures for observations before and during the period of thyroid feeding seem insignificant. However, the actual changes that occurred were generally large enough to leave no doubt about the genuineness of the results.

Thus, in dog 12, while the average temperature during the period of thyroid feeding does not appear to differ from that during the control period, actually it had reached 102.7° F. at the time that the animal was sacrificed for determination of the epinephrine output from the adrenals. A similar gradual increase

19	M	11.2	8.6	0.9	12.5	53	80	100.5	101.3	1.51	2.48	0	0.00013
25	F	7.3	5.7	1.1	12.5	71	83	100.3	101.4	1.71	2.54	++	0.00010

was observed in heart rate in all the animals. Water intake and urine output were increased in four of the animals. The two dogs (Nos. 19, 25) in which observations of the basal metabolic rate were made showed an average increase of 61 per cent and 49 per cent, respectively, during the period of thyroid feeding.

The rate of liberation of epinephrine from the adrenals, in the animals with experimental hyperthyroidism, was not significantly different from that of the control, normal dogs. It was well within the range of epinephrine output usually observed in normal animals when measured directly by this method. In a small number of preliminary experiments on dogs, subjected to thyroid feeding for shorter periods, one of us (J. M. R.) obtained similar results.

In four cats, studied by Mr. George N. Stewart, prolonged thyroid feeding led to marked loss of weight in two, moderate loss in one, and no loss in one. In all of the animals, at the end of the experimental period, he found the epinephrine output from the adrenals very close to the average for normal cats, as determined by the same method.

Our experiments indicate that thyroid feeding does not cause a significant change in the rate of liberation of epinephrine from the adrenals, even when it produces a definite hyperthyroid state in the experimental animal.

DISCUSSION

Recent experimental investigations support the concept of functional interrelationship between various endocrine organs. This is especially true concerning interdependence between the anterior hypophysis and certain other glands. Evidence in support of a hypothetical interrelationship of a mutual character between two glands is incomplete unless there is provision for maintenance of a physiologic balance between the interrelated functions. Existence of an interrelationship limited to mutual stimulation (or depression) alone, without a control mechanism to limit or prevent continued and increasing overactivity (in either direction) of the related organs, appears to us as unlikely.

In the case of thyroid-adrenal interrelationship, a mutual stimulating action is believed to exist. The literature, largely clinical, generally supports this view. The experimental evidence in support of this hypothesis, however, is susceptible to serious criticism: it is not quantitative; attempts to measure epinephrine in blood were made with inadequate methods; indirect, nonspecific reactions have been relied upon as indications of increased epinephrine output from the adrenals.

In blood serum of individuals with exophthalmic goiter, demonstrable increase in epinephrine was reported by Kraus and Friedenthal,⁴ Fraenkel,⁵ and Bröking and Trendelenberg⁶ employing biological test objects. On the other hand, Gottlieb,⁷ who tested plasma, was unable to obtain epinephrine reactions. O'Connor⁸ demonstrated that the positive reactions were artifacts due to development of substances in clotting blood which gave reactions similar to epinephrine on the test objects.

Improper interpretation of such reactions may lead to serious error. Thus, Fraenkel,⁵ obviously having employed rabbits' uterus segments without adequate control observations, concluded from the reactions obtained that serum

from systemic blood of normal individuals contains approximately 1:400,000 epinephrine, and that corresponding serum from patients with Basedow's disease contains four to eight times this amount. Arithmetical calculation indicates that he was misled by his tests. A concentration of 1:400,000 in the serum of systemic blood would correspond to approximately 1:2,000 in adrenal blood serum. Accordingly, in Basedow's disease concentrations corresponding to 1:500 to 1:250 adrenalin would be present in the adrenal vein blood serum, which seems highly improbable if not indeed impossible. The epinephrine concentration, reported by Fracnel, for normal systemic blood is about 200 or more times as great as that found by Rogoff and Marcus⁹ to be capable of effecting hemodynamic and other, sometimes toxic, reactions.

The tonus-increasing action on rabbit's uterus (and intestine) or on a vascular preparation (frog perfusion method) has been shown by Stewart¹⁰ to be a serum effect, obtainable with unclotted blood, serum, or plasma. Epinephrine, however, produces inhibition of tone and contractions on rabbit's intestine, and the opposite on the nonpregnant or virgin uterus. This fact, indeed, incorporated in the method developed by Stewart and Rogoff, constitutes an important advantage over any other method at present available for quantitative assay of epinephrine in blood. It permits the elimination of artifacts produced by substances (or conditions) other than epinephrine, which yield epinephrine-like reactions on the intestine, uterus, vascular preparations, or denervated structures.

With sensitive test objects, Stewart¹⁰ was unable to detect epinephrine in systemic blood obtained from a case of Grave's disease. Rogoff and Wasserman¹¹ obtained negative results in tests for epinephrine on systemic blood from patients with hypertension. Rogoff and Goldblatt¹² were unable to detect the presence of thyroid hormone in blood obtained from the thyroid vein during surgical operations for goiter; they employed the sensitive endpoint reaction in their tests.

Various attempts have been made to study the influence of thyroid extracts or thyroxin on the epinephrine output from the adrenal glands. None of these offer quantitative data. Ott and Scott¹³ injected crude thyroid extracts and tested vena cava blood obtained through a catheter inserted through the femoral vein. Zunz and La Barre¹⁴ performed crossed-circulation experiments in which intravenous injection of thyroxin was followed by determinations of the blood sugar level. They concluded that a gradual augmentation of epinephrine output occurs, which is associated with hyperinsulinemia caused by the thyroxin. Quantitative measurements of epinephrine output were not made.

Kuriyama¹⁵ found no evidence that the acidosis induced in rabbits by thyroid feeding is induced by hypersecretion of epinephrine. Results obtained by histologic examination of the adrenals, e.g., Herring,¹⁶ Cramer,¹⁷ cannot be relied upon as an indication of the amount of epinephrine liberated by the glands. Like observations on the epinephrine load of the glands, they can indicate only the balance between production and liberation and do not indicate the output.

Gley and Quinquaud¹⁸ obtained adrenal blood from the adrenal veins and studied its pressor effects when injected into the circulation of a test animal.

They found no significant difference between the effects of control specimens and specimens obtained after injection of thyroid extracts. Their experiments were the most direct but lack quantitative significance since they did not take account of possible changes in the rate of blood flow through the adrenals at the time of collection of the blood specimens.

In experiments where the observations were made shortly after administration of thyroid extract or thyroxin, it may be pointed out that thyroid effects could hardly have been expected. Kunde² demonstrated that changes in the basal metabolic rate do not occur until from seven to twelve hours after administration of thyroid. In our experiments thyroid feeding was continued for sufficiently long periods to cause definite thyroid reactions. Quantitative determinations of the rate of liberation of epinephrine from the adrenals were made with a method that has proved reliable over a period of many years.

Epinephrine output in the hyperthyroid animals was not different from that in normal, control dogs. If epinephrine secretion from the adrenal glands is at all related to the phenomena associated with hyperthyroidism, it appears more likely that under these conditions the sympathetic nervous system might become more sensitive to the action of epinephrine in the amounts normally liberated. This possibility is suggested by the observations of Asher and Flack¹⁹ and others, and by the Goetsch²⁰ clinical test for hyperthyroidism.

SUMMARY

1. Experimental hyperthyroidism was produced in dogs by feeding desiccated thyroid for periods ranging from three weeks to three months. At the end of these periods the animals were sacrificed for determination of the rate of liberation of epinephrine from the adrenal glands.

2. Quantitative measurements of the epinephrine output from the adrenals showed that there is no detectable change in the rate of liberation of epinephrine. The output was within the same range as is found in normal, control animals.

THE BLOOD SEDIMENTATION RATE IN HEALTHY GIRLS*

LOUIS BENSON, M.D., AND EDWARD J. ROGERS, M.D.
PITTSFORD, VT.

SINCE the fundamental studies of Fåhræus in 1917, the erythrocyte sedimentation test has become a very commonly used tool of the physician.¹ Despite the many possibilities of error in execution and interpretation, its comparative value has not diminished.

Abnormal sedimentation rates have been described in patients suffering from acute and chronic infections, malignancy, endocrine disturbances, infarction, and allergy. Pregnancy and meteorologic conditions seem to cause an increase in the velocity of sedimentation.² On the other hand, simple catarrhal inflammations, functional disorders, focal infections, and skin diseases do not seem to influence this test.

Most studies published have been concerned with the variations of the blood sedimentation rate in disease. The references listing physiologic changes in health describe a small variation between the two sexes, and an insignificant change in old age. A recent study of the rate in healthy young people disclosed a range of 1.0 to 30.0 mm. in 95 per cent of the cases, with a mean of 10.0 mm. in forty-five minutes. When plotted, a skew curve resulted, with the 15 mm. rate in forty-five minutes as the upper limit in 80 per cent of all the cases.³ The Westergren pipette and the potassium oxalate method was used in this particular study.

In another examination of healthy men and women, weekly changes were found, but always within normal limits.⁴

*From the Department of Medicine and Preventive Medicine, University of Vermont, College of Medicine.
Received for publication, March 5, 1940.

Normal limits for the blood sedimentation rate by the Westergren method are 1.0 to 3.0 mm. per hour for men, and 4.0 to 7.0 mm. per hour for women. The Cutler method assumes 2.0 to 10.0 mm. per hour as the average for women in health.^{5, 6}

In a further attempt to obtain more accurate data concerning the blood sedimentation rates in healthy people, a total of 360 presumably healthy girls were studied with this idea in mind.

TABLE I
BLOOD SEDIMENTATION RATES OF 327 HEALTHY GIRLS

25	1	0	0	0	0	0	0	0	0	0	0	1

METHODS

Inasmuch as it has been shown that the erythrocyte sedimentation rate is reasonably the same by the methods of Linzenmeier, Westergren, and Cutler, the latter method, being available, was used.⁷

The 5 c.c. graduated tube was used, with 3 per cent sodium citrate as the anticoagulant. Necessary corrections were made for anemia. All the bloods were withdrawn between 10:00 and 11:00 A.M., and the tests were performed the same morning.

All the young women studied were between 10 and 20 years of age, and were born in the state of Vermont. Each girl was given the usual physical and laboratory examinations, which included routinely, serologic tests for syphilis and undulant fever, tuberculin test, chest x-ray film with serial retakes when indicated, and blood morphology examinations in all cases of increased sedimentation rates.

A definite attempt was made to rule out any hidden chronic infections as syphilis, tuberculosis, undulant fever, localized suppuration, and rheumatic fever. All these girls were followed for at least four months after the

determination of the original sedimentation rate to limit the possibility of any disease process appearing subsequently that may have been present at the time of the original examination.

No sedimentation rate was determined during a period of common cold, two days before or following menses, or when it was thought peripheral dental infection or tonsillitis might be present, despite previous statements that no appreciable elevation in rate is present in these conditions.⁸

RESULTS

There are included in this report the blood sedimentation rates of 327 presumably healthy girls. All these girls were known not to have been ill at any time within four months after the blood was withdrawn for the original test.

As can be seen from Table I, 92 per cent of these girls had sedimentation rates between the limits of 2 mm. and 13 mm. per hour, whereas the rates of 8 per cent of the girls ranged from 14 mm. to 25 mm. per hour. The median fell at 7 mm. per hour.

CONCLUSION

Normal variations of any test must be ascertained before such a test can be relied upon for diagnosis.

This study suggests that in young women the blood sedimentation rate is variable, and that about 10 per cent of healthy young women may have sedimentation rates of greater velocity than the average arbitrary range.

The diagnostic value, therefore, of the erythrocyte sedimentation rate must be guided by these normal variations.

CLINICAL CHEMISTRY

STUDIES IN DYSTROPHIA MYOTONICA*

V. CREATINE AND CREATININE EXCRETION†

ROBERT C. LEWIS, JR., PH.D., ABE RAVIN, M.D., AND ROBERT C. LEWIS, PH.D.
DENVER, COLO.

AN ABNORMALITY in the metabolism of creatine and creatinine has been reported in several of the primary myopathies, as well as in certain conditions which secondarily affect the skeletal muscles. This abnormality may be manifested in several ways: (1) The creatine content of the muscles may be subnormal. (2) The ability to retain ingested creatine may be decreased. (3) Even on a creatine-free diet there commonly occurs a creatinuria which, according to Milhorat and Wolff,^{9, 10} is an expression of the total mass of improperly functioning muscle rather than of the amount of muscle which has actually degenerated. (4) The excretion of creatine may be greatly augmented when glycine is administered orally. (5) If there are extensive muscular atrophy and degeneration, creatinine excretion, which is dependent upon the total muscle mass, may be considerably below normal. All these symptoms are observed to a marked degree in progressive muscular dystrophy.

The recent discovery at the Colorado General Hospital and Outpatient Clinic of a number of patients with dystrophia myotonica from five different families‡ has given an unusual opportunity for studies of this disease,^{18-20, 22, 23} which is apparently not so rare as is commonly believed (cf. Stevenson in Cecil's *Textbook of Medicine*²⁴). In the course of these studies it was decided to investigate the excretion of creatine and creatinine in some of the patients and to compare the findings with those in previous reports of this disease and of progressive muscular dystrophy.

The literature on the metabolism of creatine and creatinine in dystrophia myotonica is summarized in Table I. From this table the following observations may be made: (1) According to one investigator¹⁵ creatine phosphate in resting muscles is below normal and its breakdown during contraction is subnormal. (2) Creatine tolerance is decreased in some cases. (3) Creatinuria is slight to moderate in degree and may or may not be augmented by glycine adminis-

*From the Departments of Medicine and Biochemistry, University of Colorado School of Medicine and Hospitals, Denver.

†The results given in this paper for patients J. M. and N. P. were taken from a thesis presented by Robert C. Lewis, Jr., to the Graduate School of the University of Colorado in partial fulfillment of the requirements for the degree Master of Science, August, 1937. A preliminary report of the work on patients J. M. and N. P. was made at the meeting of the American Association for the Advancement of Science at Denver, June, 1937.

Received for publication, May 6, 1940.

‡A patient from a sixth family has been admitted to the hospital since these studies were made.

tration. According to Milhorat and Wolff,¹³ the excretion of creatine is much less than in patients with progressive muscular dystrophy who show similar degrees of muscular disability. (4) Creatinine excretion is variably decreased.

EXPERIMENTAL

The excretion of creatine and creatinine was studied in one woman (J. M.) and two men (N. P. and R. B.) with dystrophia myotonica. J. M., female, aged 44 years, had severe myotonia in the hand grasps, and moderate atrophy of the forearms, hands, and lower extremities. She was still menstruating although somewhat irregularly. Her basal metabolic rate was minus 10. N. P., male, aged 52 years, had slight myotonia, marked atrophy of the forearms and hands, and

moderate atrophy of the lower extremities, but no evidence of testicular atrophy. His basal metabolic rate was minus 20. R. B., male, aged 27 years, had moderate myotonia, moderate atrophy of the forearms and hands and slight atrophy of the lower extremities. His testicles were small and questionably atrophic. His basal metabolic rate was minus 30. A more detailed description of these patients may be found in an earlier paper.²⁶

Determinations of creatine and creatinine in twenty-four-hour urines (7:00 A.M. to 7:00 A.M.) were made during a preglycine period, during glycine administration, and after discontinuing glycine. The amino acid was administered by mouth three times daily after meals in amounts as high as 30 Gm. per day. No attempt was made in any case to control the diet.

Preformed creatinine was determined by the Folin colorimetric method³ using a Duboseq colorimeter and matching through a piece of cobalt glass. Total creatinine was determined by the same method after the urine had been autoclaved with picric acid according to the method of Folin.⁵ Creatine was calculated by multiplying the difference in the above determinations by the factor 1.159.

Average values for the different experimental periods on these three patients are shown in Table II.

The woman patient, J. M., showed a creatinuria which was significantly higher than the average daily excretion of the normal women studied by Rose.²¹ In this patient creatine excretion increased definitely during glycine administration; the increase was prompt and the excretion remained high as long as glycine was fed, a period of eight months. The amount of creatine in the urine depended apparently on the amount of glycine fed, for it increased progressively as the dosage of glycine was raised and fell when the dosage of glycine was lowered. Three weeks after cessation of glycine administration the creatinuria had returned almost to the preglycine level.

Both of the men patients showed a slight initial creatinuria. The amounts of creatine excreted were approximately the same as those reported in patients with dystrophia myotonica by most other investigators, but these values are not as great as some of those reported for normal men by Taylor and Chew²⁵ and by Milhorat and Wolff.¹¹ In neither man was there any immediate effect on creatine excretion when glycine was fed; in patient R. B. there was no effect at any time. However, after glycine had been fed to patient N. P. for five and one-half months, the creatinuria had increased from the preglycine level of 0.06 Gm. per day to 0.11 Gm. per day, and it was still at this higher level two weeks after cessation of glycine feeding. Such a small increment in creatine excretion may have little significance, however, since Braestrup³ found that 14 Gm. of glycine daily produced a maximum excretion of 0.080 Gm., 0.094 Gm., and 0.100 Gm. per day in three normal men who had shown no initial creatinuria. On the other hand, Braestrup³ found that glycine produced no creatinuria in another normal man, and Milhorat and Wolff¹¹ reported that glycine feeding did not increase the creatine excretion of normal men who showed a preglycine creatinuria comparable to that of our two men patients. These reports were all concerned with relatively short periods of glycine feeding; no reports were found that showed

the effect on creatine excretion of administering glycine to normal men for such a prolonged period and in such large amounts as in our experiments.

Patient R. B., whose creatinuria was not augmented by glycine alone, had no greater excretion of creatine when anterior pituitary extract or testosterone propionate* was administered simultaneously with glycine. These results differ from those of Slauek²³ in a patient with dystrophia myotonica but are in accord with those of Milhorat and Wolff¹² in patients with myasthenia gravis. Slauek found that his patient, who showed no increase of creatine excretion in response to glycine alone, had a markedly increased creatinuria when testicular extract was administered simultaneously with glycine. Milhorat and Wolff reported that the administration of anterior pituitary extract to two patients with myasthenia gravis had no effect on creatine excretion. It is interesting to observe that Pizzolato and Beard¹⁷ have reported an increase in the creatine content of muscle and in the excretion of creatine when anterior pituitary extract is administered to normal rats, and also an increase in the creatine content of muscle when testicular extract is given.

Creatinine excretion in all three patients fluctuated considerably throughout the experiments and was not significantly affected by glycine administration. Part of the variation may be ascribed to changes in diet from day to day. The creatinine coefficient was within the normal range in two of the patients but was low in patient N. P., who showed the greatest degree of muscle atrophy.

SUMMARY AND CONCLUSIONS

1. The excretion of creatine and creatinine and the effect of glycine administration thereon were studied in three patients, one woman and two men, with dystrophia myotonica.

2. Creatinuria was present in all three patients during a preglycine period. The amounts of creatine excreted by the woman were greater than normal; the amounts excreted by the two men were small and probably within normal limits.

3. Glycine administration produced an increase in the amounts of creatine excreted by the woman and by one of the men. In the woman a definite increase occurred promptly; in the man the rather slight increase was slow to develop and of questionable significance. Neither the administration of glycine alone, of glycine and anterior pituitary extract, nor of glycine and testosterone propionate affected the excretion of creatine in the other man.

4. The excretion of creatinine was subnormal in the patient who showed the greatest degree of muscle atrophy but was normal in the other two patients. It was not significantly affected by glycine administration in any of the three patients.

5. Although the data obtained are insufficient for drawing definite conclusions, they seem to augment the evidence from previous reports that the slight to moderate creatinuria which may be observed in dystrophia myotonica is neither as constant nor as striking a finding as that observed in progressive muscular dystrophy, and is less strongly affected by administration of glycine than in the latter disease.

*The testosterone propionate (oretan) was furnished through the kindness of Dr. Max Gilbert of Shering Corporation.

BIOCHEMICAL STUDIES OF THE BLOOD OF DOGS WITH N-PROPYL DISULFIDE ANEMIA*

HAROLD H. WILLIAMS, PH.D., BETTY NIMS ERICKSON, M.S.,
ELIOT F. BEACH, PH.D., AND ICIE G. MACY, PH.D., DETROIT, MICH.

WITH THE ASSISTANCE OF

IRA AVRIN, M.S., MARION SHEPHERD, A.B., HELEN SOUDERS, M.S.,
D. MAXWELL TEAGUE, B.S., AND OLIVE HOFFMAN, PH.D.

PREVIOUS studies by this laboratory of pernicious anemia¹ and the hemolytic and hypochromic anemias of childhood² have shown that chemical changes occur in the blood which are indicative of abnormal erythrocyte composition or structure. Further study and elucidation of the chemical structure of the normal erythrocyte has been made possible by the development of a method³ for the preparation of posthemolytic residue or stroma practically free of hemoglobin. Chemical studies of this material have revealed that the stroma of the normal erythrocyte is a protein-lipid complex of similar composition for various mammalian species.^{4, 5} Moreover, it has been demonstrated that the lipid distribution in the posthemolytic residue is similar to that in the intact erythrocyte.⁴

In view of the indications of abnormal erythrocyte structure in certain anemias, it seemed desirable to secure sufficient stroma for a complete chemical investigation of its character, together with hematologic and chemical observations on the intact erythrocyte. At present enough blood from human patients with anemias for preparation of sufficient stroma is practically impossible to secure. It is possible, however, to develop an experimental anemia in animals: a procedure which offers the advantages of more rigid control, but has disadvantages in that the particular types of anemia occurring in human beings which present the most striking changes in erythrocyte structure^{1, 2} are not amenable to experimental development. Simple hypochromic anemia (iron deficiency), which results in impaired hemoglobin formation, does not appear to affect the chemical design of the erythrocyte.² Hemolytic anemias, which are accompanied by definite alterations in the hematologic pattern of the blood, are produced in animals by certain drugs causing red blood cell destruction. Such an anemia offers an excellent opportunity for correlated hematologic, chemical, and stroma studies which are important in view of the marked abnormalities of erythrocyte composition found in the congenital hemolytic anemias of childhood.²

Sebrell⁶ originally observed that onions would produce a severe anemia in dogs. Grulhitz^{7, 8} confirmed this and showed further that the action resided in

*From the Research Laboratory of the Children's Fund of Michigan, Detroit.

A preliminary report of this investigation was presented before the Ninety-Sixth meeting of the Division of Medicinal Chemistry of the American Chemical Society, Milwaukee, Wis., Sept. 5 to 9, 1938.

Received for publication, June 3, 1940.

the onion oil, probably due to the allyl propyl disulfide, the main constituent of onion oil. In a study of different disulfide compounds Grulhitz⁸ demonstrated that N-propyl disulfide produced a severe anemia in dogs and that any desired degree of anemia can be maintained for a long period of time, depending on the regular administration of definite amounts of the disulfide, a significant factor in studying the influence of anemia on erythrocyte structure.

Grulhitz⁸ has described the changes in the hematologic picture induced by this type of anemia, but thus far no chemical observations have been reported. Furthermore, the possibility of using N-propyl disulfide to control polycythemia in human beings⁹ points to the necessity of studying not only the hematologic and chemical changes occurring in the blood but also the pathologic changes in the tissues as well. This report includes, therefore, detailed chemical and hematologic examinations of the blood and pathologic observations of certain tissues, in addition to the effect of anemia on the composition of erythrocyte stroma.

EXPERIMENTAL

Two originally healthy dogs were maintained in a moderate-to-severe degree of anemia for a period of over three months by the administration of N-propyl disulfide ($\text{CH}_3\text{CH}_2\text{CH}_2\text{S-SCH}_2\text{CH}_2\text{CH}_3$).⁶ Previous to beginning the study, the animals were immunized with *B. bronchisepticus* vaccine. The dogs were fed a complete, nutritive diet and given the disulfide in gelatin capsules at intervals and dosages, as indicated in Chart 1. Hematologic examinations consisting of hemoglobin determinations, red blood cell and white blood cell counts were made at intervals during the course of the experiment. These values, plotted in Chart 1, show the degree and maintenance of the anemias as the study progressed. Samples of blood (60 c.c.) for chemical analysis were taken at the beginning of the experiment before disulfide was administered, frequently in the first month during the period of adjustment, and at the end of the study, as indicated in Chart 1. Determinations of red blood cell count, hemoglobin content, hematocrit value, red blood cell diameter, specific gravity, and water content were made, from these, corpuscular volume, weight, thickness, area, hemoglobin, and water were calculated. The chemical determinations on the blood included the following: serum calcium and inorganic phosphorus, total protein of the plasma; sodium, potassium, and chloride content of serum and cells and the complete lipid distribution of the plasma and erythrocytes. The methods used were the same as those in previous studies reported from this laboratory.^{10, 11}

Just preceding completion of the experiment, x-rays[†] of the skull, spine, and leg bones of both dogs were made. When the experiment was terminated, the dogs were exsanguinated under light ether anesthesia and the blood was used for the preparation of erythrocyte stroma.³ Tissues were preserved for histopathologic and chemical study.

⁶This study was made possible through the courtesy and facilities of Parke, Davis & Co., Detroit. E. A. Sharp, M.D., medical director, suggested the use of N-propyl disulfide to produce the anemia and gave helpful suggestions during the course of the investigation. L. T. Clark, Ph.D., director of the biological laboratories, made the animals available and the investigation possible. O. M. Grulhitz, M.D., pathologist, prepared the anemic animals, made the hematologic examinations on the blood, took the blood and tissue samples, and gave helpful advice in the preparation of the manuscript.

[†]The x-ray films were taken and read by Lawrence Reynolds, M.D., roentgenologist, Harper Hospital, Detroit.

RESULTS

The clinical blood picture during the course of the anemia is given in Chart 1 and demonstrates the marked anemia producing powers of N-propyl disulfide and, furthermore, shows the closely parallel responses of the two dogs to the drug. Table I presents the hematologic observations on the blood samples taken for chemical analysis. Before administration of the disulfide the two dogs had blood counts of 6.5 and 7.1 millions per cubic millimeter, respectively. During the first month of the study these values ranged between 1.7 and 4.6 millions, after which the level approximated 3.5 millions for both animals until the termination

Chart 1.

of the experiment. Specific gravity, water, and protein contents of the plasma showed no change as a result of the anemia (Table II), which indicates that the blood concentration was unaffected. All corpuscular measurements disclosed a larger and heavier cell in the anemic state. The cell volume was about 80 c. μ in the animals before anemia was induced, but with the progress of the anemic condition the cell volume increased to 90 c. μ or over. Likewise, the corpuscular weight was 90 micromicrograms or less in the nonanemic bloods, but increased to a weight of 98 micromicrograms or more in the anemic condition. Similarly, the cell diameter and the calculated cell area were increased with the anemia, whereas the computed number of cells per gram of cells was decreased. Although part of

the increased weight may have been due to a larger quota of hemoglobin per cell, it is accounted for chiefly by an augmented water content. Whereas the corpuscular water of the normal dog erythrocytes averaged 55 micromicrograms, it rose as high as 76 micromicrograms during the anemia, changes accompanied are shown by a corresponding decrease in specific gravity. These alterations indicate that the cells underwent osmotic swelling, which is in accord with their increased fragility in hypotonic sodium chloride solutions. Hemolysis was evident in 0.62 per cent sodium chloride (the highest concentration used) in comparison with normal values of 0.50 to 0.54 per cent given by Haden.¹²

The sodium, potassium, and chloride distribution of the blood serum and cells, together with the serum calcium and inorganic phosphorus values, are given in Table II. The plasma mineral constituents, except the chloride, appear to be unaffected by the induction of the anemia. The chloride content of both the serum and erythrocytes was consistently lower after three months of anemia. Serum chloride was above 100 meq. per liter in the animals without anemia, while at the end of the study it was 96 meq. or less. Similarly, the chloride content of the erythrocytes was reduced markedly, from above 50 meq. in the animals when nonanemic to below 30 meq. after three months' duration of the anemia.

The advantages of expressing the erythrocyte composition in terms of an individual corpuscle rather than on the unit weight basis has been demonstrated in the anemias.^{1, 2} In this study, calculation of the corpuscular mineral concentration emphasizes further the lowered chloride content of the erythrocyte at the termination of the experiment (Table II). In addition, there is evidence of an elevated base (sodium and potassium) content per cell which is not particularly apparent from the values expressed in milliequivalents per liter of erythrocytes. Before anemia the dogs had 72 and 88 $\times 10^{-13}$ meq. of sodium per cell, whereas after three months in the anemic state, there were 99 and 104 $\times 10^{-13}$ meq. of sodium, respectively, in comparison with normal values of 91 to 96 $\times 10^{-13}$ meq. Likewise, potassium was elevated after duration of the anemia to 17 and 20 $\times 10^{-13}$ meq. of potassium in contrast to a normal value of 3 to 6 $\times 10^{-13}$ meq. per

**Represents the concentration of an average single red blood cell.

cell. The elevated corpuscular base, together with the lowered chloride, indicates an excess cation content or the presence of increased amounts of an undetermined anion, alterations which are similar to those noted in various types of human anemias.^{1, 2, 13}

The anemia was accompanied by changes in the erythrocytes indicative of osmotic swelling. Calculation of the mineral composition on the basis of milliequivalents per liter of cellular and plasma water (Table III) bring out the fact that normally, as well as in the anemia, the sodium is almost evenly distributed between the water of plasma and cells. Normally, the potassium is likewise equally partitioned, but as the anemia progresses it becomes more concentrated in the cells. On the other hand, although the chloride is lowered in the water of both plasma and cells, it is more markedly diminished in the cells, which is in agreement with the swelling of the cell and its increased fragility.

The lipid composition of the plasma and erythrocytes (mg. per 100 c.c.), together with the calculated corpuscular concentration (mg. $\times 10^{-12}$ per cell), are given in Table IV. The total lipid content of the plasma of the dogs before

anemia ranged between 446 and 680 mg. At the end of the study the experimental animals had a plasma lipid content of 412 and 419 mg. Of the various components of the total lipid, free cholesterol appears to have been unaffected by the induction of the anemia; on the other hand, neutral fat was increased and cholesterol esters and phospholipid were decreased. Although dogs 146 and 148 had a lower plasma neutral fat, 69 and 22 mg., respectively, before induction of the anemia as compared to an average of 137 mg. for the animals that received no drug, they had concentrations of 173 and 161 mg. at the termination of the experiment. The cholesterol ester concentration of the plasma ranged between 119 and 174 mg. in the nonanemic animals. After three months of N-propyl disulfide the anemic dogs (146 and 148) had a plasma content of 70 and 77 mg. of cholesterol esters, respectively. Similarly, the plasma phospholipids ranged between 270 and 357 mg. in the animals when healthy, and fell after three months of anemia to 136 mg. in dog 146 and 153 mg. in dog 148. Separation of the phospholipid fraction into cephalin and choline phospholipid (lecithin plus sphingomyelin) showed that, whereas both follow a trend similar to the total phospholipid, the cephalin appears to be affected to a greater and more consistent degree. In fact, no cephalin could be detected in the plasma of the dogs after being kept anemic for three months with disulfide. These parallel changes in the plasma

lipids of the two dogs—lowered phospholipid and cholesterol esters and increased neutral fat—are typical of the changes found in the plasma lipids of different types of anemias in man and animals.^{1, 2, 14}

A study of erythrocyte lipids (on the basis of milligrams per 100 c.c. of cells) indicates that although the total lipid concentrations in the two animals varied widely during the first month of the anemia, the values at the end of the experiment appear comparable to those obtained before N-propyl disulfide was given.⁴ The neutral fat concentration shows the widest variation of any of the lipid components, but without relation to the anemia. Free cholesterol seems to have been increased, and the total phospholipid appears to have undergone no consistent change as the result of the anemia.

Due to the changing size and weight of the red blood cells in anemia, however, determinations on the unit weight basis may obscure what is actually occurring in the individual corpuscle. Calculation of the composition of the individual cell, therefore, gives a truer picture of the chemical changes in structure, well illustrated by the present study. Both dogs exhibited an increased corpuscular concentration of total lipid not evident from the data on total lipid per 100 c.c. of erythrocytes. Neutral fat data show no change attributable to the anemia. The increase in free cholesterol is brought out more strikingly in the corpuscular concentration. The animals which received no disulfide had a range of 85 to 115 mg. $\times 10^{-12}$ per cell, and the experimental dogs had values of 50 and 106 $\times 10^{-12}$ before administration of the drug. At the end of the three months of anemia there was an increase to 151 and 145 mg. $\times 10^{-12}$ per cell, respectively.

The rise in cholesterol ester content of the corpuscle, noted in previous studies of anemia,^{1, 2} was observed in dog 146; the cholesterol esters increased from 17 $\times 10^{-12}$ mg. per cell to 121 $\times 10^{-12}$ mg. at the end of the experiment. The other experimental animal (dog 148) showed little or no change in the corpuscular content of cholesterol esters.

The concentration of the corpuscular phospholipid was increased in both dogs as a result of the anemia, in contrast to the observations per liter of cells. The average concentration of phospholipid per single cell was 295 $\times 10^{-12}$ mg. for the untreated animals and 293 and 298 $\times 10^{-12}$ mg., respectively, for dogs 146 and 148 before administration of the disulfide.

During the first month of anemia the total phospholipid was extremely elevated at times (853 and 642 $\times 10^{-12}$ mg.), producing average values of 476 and 432 $\times 10^{-12}$ mg., larger amounts than after three months in the anemic state when the values were 326 and 252 $\times 10^{-12}$ mg. per cell, respectively, for dogs 146 and 148. When the total phospholipid is separated into its individual components, salient differences are revealed. Cephalin was significantly elevated at times within the first month, whereas the choline phospholipids (lecithin plus sphingomyelin) reached both minimum and maximum values. There may be a close relationship between the presence of immature red blood cells, the elevated total phospholipid, and the individual phospholipid partition at the initiation of the anemia. Rapid erythrocyte destruction by the drug is followed by an outpouring of reticulocytes⁵ which in this study occurred during the first month. With longer duration of the anemia the marked decrease in corpuscular cephalin and

elevated choline phospholipid indicate a definite change in the structure of the red blood cell. These results support recent views that hemolytic agents injure directly the structure of the mature erythrocyte, making it more susceptible to normal hemolytic processes in the body.¹⁵

In view of the neurologic manifestations which frequently accompany anemia, detailed lipid analyses and histopathologic studies* of the brains were made (Table V). No significant differences are evident in any of the lipid constituents except cerebrosides, which was slightly higher, and neutral fat, which was lower in the brains of the anemic dogs. Cerebroside values† for the anemic dogs were 1.6 and 2.2 per cent (wet weight) as compared to 1.0 and 0.9 per cent for normal dogs; neutral fat values were 0.6 and 1.2 per cent as compared to 2.2 and 1.4 per cent, respectively. The brains contained (on the wet weight basis) 5 per cent total phospholipid, 2 per cent free cholesterol, and negligible amounts of cholesterol esters. Cephalin constituted the major portion of phospholipid (60 per cent of the total), with the remaining 40 per cent about equally partitioned as lecithin and sphingomyelin.‡

Histopathologic examinations§ of the liver, spleen, and bone marrow of each animal showed that conspicuous changes had occurred with the anemia. The livers were found to be congested and contained pigment deposits. There was no evidence of an infectious process. The spleens contained a large amount of light brown pigment and the sinusoids were distended with red blood cells to such a degree that most of the normal splenic structure was indistinct. The appearance

*Each brain was divided into six separate sections, which were analyzed separately and then totaled for values on the entire brain. Specimens of the separate sections of each brain were taken for histopathologic examination by Gabriel Steiner, M.D., research professor of neurology and neuropathology, Wayne University College of Medicine, Detroit, and the results will be related with the chemical analyses in a later report.

†Cerebrosides were determined by a modification of the Kimmelstiel-Kirk¹⁶ method.

‡Micro methods for lecithin, cephalin, and sphingomyelin developed in this laboratory are described in a separate publication.¹⁷

§The bone marrow smears were observed by Pearl Lee, M.D., hematologist, and the liver and spleen by Martha Madsen, M.D., pathologist, Children's Hospital of Michigan, Detroit.

was similar to the active stage of hemolytic icterus. Although x-ray examination* of the bones of the animals failed to reveal any noticeable changes, the bone marrow smears showed an increase in nucleated red blood cells and neutrophilic myelocytes, a picture of a hyperactive bone marrow. These results confirm those of Gruhzit⁹ on the hemolytic nature of the disulfide anemia.

A review of the physical and chemical changes which occurred in the erythrocytes as the result of the disulfide anemia discloses further similarities to the abnormal red blood cells in active hemolytic icterus²; the enlargement of the cell accompanied by increases in fragility, water, and total base content is particularly analogous.

TABLE VI

LIPID AND PROTEIN COMPOSITION OF POSTHEMOLYTIC RESIDUE OF NORMAL AND ANEMIC DOG BLOOD

(Per cent of dry weight)

Tryptophane	1.4	1.3

*Protein calculated on basis of total stroma.

†Per cent of total nitrogen of lipid-free stroma.

A more direct approach to the chemical changes which occur in the erythrocyte structure can be made by a study of the composition of the posthemolytic residue or stroma of the red blood cell.³⁻⁵ In order to secure a sufficient amount of this material for detailed lipid and protein analysis, it was necessary to combine all the blood that could be drawn from the two dogs with N-propyl disulfide anemia at the end of the study. The lipid and protein analyses of the stroma from the combined blood of the anemic animals (146 and 148) are presented in Table VI, together with similar analyses on the stroma obtained from the combined blood of two untreated animals.

The stroma isolated from the cells in anemia had a total lipid content of 11.6 per cent as compared to 16.9 per cent for that of the normal dog stroma. Likewise, the neutral fat (which includes cerebrosides) and free cholesterol fractions were lower in the stroma from the anemic dogs. Noticeable, however, is the appearance of cholesterol esters. In the normal dog stroma no cholesterol esters could be detected. In the anemic stroma there was found to be 1.7 per cent cholesterol esters. Both cephalin and lecithin components of the phospholipid were lower, paralleling the lower phospholipid content, whereas the remaining

*See footnote † page 997.

phospholipid constituent, sphingomyelin, was approximately the same in the stroma from the normal and anemic dogs. The diminished cephalin content of the stroma is in accordance with that observed for the erythrocyte as a whole, but the decreased lecithin indicates that not all of this phospholipid within the anemic cell is combined with the stroma. The decreases in total phospholipid and free cholesterol, together with the appearance of cholesterol esters, are indicative of degenerative and retrogressive tissue changes¹ and imply a defective or impaired structure of the erythrocyte in the anemic state.

The total protein content, in contrast to the lipid, was lower in the normal dog stroma (57.1 per cent) as compared to the anemic stroma (70.5 per cent). Determination of the stroma content of histidine, arginine, lysine, tyrosine, and tryptophane, showed that on the basis of these amino acids, which account for 24 to 27 per cent of the total protein nitrogen, the normal dog stromal protein is similar to the anemic stromal protein and to that from the erythrocytes of other mammalian species⁵. It appears, therefore, that the disulfide anemia has no qualitative effect on the erythrocyte stroma protein. In view of the acidic nature of this type of protein⁵ an increased proportion in the stroma, however, may be related to the elevated base content of the erythrocyte in the anemia.

SUMMARY

Correlated investigations of dogs with an experimental hemolytic anemia induced by N-propyl disulfide have included determination of hematologic, physical, and chemical characteristics of the blood; the chemical composition of the erythrocyte stroma; roentgenologic examinations of the bones and histopathologic observations of tissues.

As a result of the anemia, chloride, phospholipid and cholesterol esters were lowered in the serum, or plasma, and the neutral fat content was increased. The plasma lipid changes were similar to those observed in the hemolytic anemias of childhood and pernicious anemia and appear to be typical of all anemias.

In the N-propyl disulfide anemia the erythrocyte was larger and heavier, as shown by increased volume, weight, and diameter of the cells; an increase in water content accompanied by a lower specific gravity attended by greater fragility indicate that the anemia caused osmotic swelling of the red blood cells.

Elevated corpuscular base and lowered chloride contents, previously noted in anemias of man, point to an excess cation content or an increased amount of an undetermined anion in the erythrocyte of an anemic subject.

Marked alteration in the cellular structure of the erythrocyte in anemia is indicated by the changes in the lipid fractions; outstanding alteration was a striking decrease in cephalin content.

The chemical composition of the erythrocyte stroma confirms the altered red blood cell structure in anemia. The stroma, a complex of lipid and protein, was changed both quantitatively and qualitatively in its lipid content; the protein fraction of the stroma in anemia was similar in composition to normal stroma but larger amounts were present. It is significant, in view of the acidic nature of the stroma protein, that the red blood cells in anemia contained greater amounts of basic minerals.

THE INFLUENCE OF THE PAROTID GLAND ON BLOOD SUGAR*

A PRELIMINARY REPORT

W. B. BRINKRANT, M.S., M.D., NEW YORK, N. Y.

THE existence of a carbohydrate-regulating hormone, secreted by the parotid gland, has been postulated by several foreign observers. Hiki¹ and his collaborators obtained parotid extracts, which, when injected into dogs, caused marked and rapid hyperglycemia. Takaes,² on the other hand, reported a hypoglycemia in animals following the injection of ether and alcohol extracts of this gland. Rosenfeld³ maintained that the hypoglycemia following the ligation of the parotid ducts is due to absorption of amylase or ptyalin, rather than to an internal secretion of an insulinlike substance. Thus biochemical studies have given rise to three differing conclusions concerning the action of parotid extracts.

Cahane and Cahane⁴ in 1924 extirpated the parotid glands of two dogs. They reported subsequent hypertrophy and hyperplasia of the islands of Langerhans. Annaps⁵ reported cure of hyperglycemia of depancreatized dogs following parotidectomy. Ferretti,⁶ on the other hand, stated that hypertrophy of the parotid glands is a compensatory mechanism; i.e., the parotids take on the function of the pancreas in the manufacture of insulin.

Injections of parotid extracts and surgical procedures on the parotid gland have had definite effects on blood sugars. These effects and the interpretations thereof have not been uniform.

The present study was undertaken, therefore, in order to study blood sugar levels and tissue changes in completely deparotidectomized animals.

EXPERIMENTAL PROCEDURES

Eight young male albino rats, weighing from 223 to 305 Gm., were used. A daily record of food consumption and weights was kept. Daily blood specimens were drawn at approximately the same time of day for a period of one week. The animals were not fasted prior to the drawing of blood, since there is no indication that greater precision in the estimation of blood sugars in rats could be secured by periods of inanition.⁷ Four rats were chosen at random for the operative procedure and four rats were used as controls. Total bilateral parotidectomies were performed on rats Nos. 3 and 5; one-sixth of the right parotid gland of rat No. 7 was left in situ. In rat No. 1 both glands were removed except for one-eighth of the right gland around which several ties were tightly placed. The modified microcolorimetric method of Benedict⁸ was used for the sugar determinations.

*From the Laboratories of the Delamar Institute of Public Health, Columbia University.
Received for publication, March 5, 1940.

RESULTS

Rat No. 3 showed a marked and significant decrease in the blood sugar from a preoperative mean of 110 mg. \pm 13 mg. per 100 c.c. of blood to 22 mg. per 100 c.c. of blood (Table I). The blood sugar remained low for three days. On the fourth day the reading returned to the preoperative level.

*Sugar is expressed in milligrams per 100 c.c.

†Number of days after operation.

Rat No. 5 also showed a marked and significant decrease in the blood sugar, from a preoperative mean of 103 mg. \pm 17 mg. per 100 c.c. of blood to 36 mg. per 100 c.c. of blood. On the seventh postoperative day the blood sugar was definitely in the preoperative level.

Rat No. 1 demonstrated a marked hyperglycemia. The blood sugar rose to 364 mg. per 100 c.c. of blood the first day postoperatively. Subsequent readings declined rapidly. By the seventh postoperative day the readings had returned to the preoperative level.

Rat No. 7 demonstrated no significant blood sugar changes throughout the course of the experiment.

Histologic Studies.—Sections were made of the liver, pancreas, adrenals, spleen, and testicles of all eight rats. No abnormal changes were found. The size, shape, and number of the islands of Langerhans of the operative animals were similar to those of the controls.

COMMENTS AND CONCLUSIONS

The postoperative blood sugars of rats Nos. 1 and 7 rule out the possibility that surgical trauma per se was responsible for the changes in the blood sugar levels. Decreased daily feedings or loss of weight alone could not have been the cause for these changes, since all four operative animals lost weight. Only the rats totally parotidectomized manifested significant blood sugar drops. We may conclude that these drops were directly due to the removal of a substance in the parotid gland which acts antagonistically to the action of insulin. Furthermore, the presence of even a minute fragment of parotid gland will prevent this fall in blood sugar, as sufficient antagonist can be elaborated by

such small fragments as were left in rat No. 7. Rat No. 1, on the other hand, demonstrated what may be considered an oversecretion of the parotid gland, due to irritations caused by ligatures passed through the gland. Subsequent tissue studies of the remnant of parotid gland in rat No. 1 revealed no structural changes.

We may conclude that the absence of parotid gland definitely lowers the blood sugar levels and, conversely, that the parotid secretes a substance that elevates the blood sugar.

Cahane and Cahane's⁴ findings of hyperplasia and hypertrophy of the islands of Langerhans were not confirmed.

The significance of the reports of Aunaps⁵ concerning the cure of hyperglycemia following parotidectomy of depancreatized dogs must remain in doubt unless a compensatory hypertrophy of unremoved pancreatic tissue in his animals can be ruled out.

The nature of the compensatory mechanism effecting the return of blood sugars to the preoperative levels is not yet understood. Further work along these lines is indicated.

SUMMARY

1. The blood sugars decreased markedly, though temporarily, in totally parotidectomized rats.
2. The blood sugar was not affected when approximately one-twelfth of the total weight of both glands was left in situ.
3. The blood sugar increased markedly, though temporarily, following ligation of part of the parotid gland.
4. All blood sugars returned to preoperative levels eight days following the operative procedure.
5. Histologic studies of the liver, pancreas, adrenals, spleen, and testicles of the deparotidectomized rats revealed no changes.

SERUM CHOLESTEROL STUDIES FOLLOWING THE ADMINISTRATION OF ACETYL- β -METHYLCHOLINE CHLORIDE BY IONTOPHORESIS*

SAMUEL MEMBER, B.S., ELLEN McDEVITT, A.B., AND JOHN B. LUDDEN, B.A., M.D.
NEW YORK, N. Y.

THAT choline is important in cholesterol metabolism has been pointed out by Best and his coworkers¹⁻³ and by other workers. Best has shown that the administration of choline prevents the fatty infiltration of the liver in rats fed fat or cholesterol. Steiner,⁴ working with 38 rabbits, some of which received cholesterol and others cholesterol and choline, found that the oral administration of 0.5 Gm. of choline daily to cholesterol-fed rabbits did not prevent the development of hypercholesterolemia when compared to the control group receiving cholesterol alone. He also concluded from this study that choline delayed, but did not prevent, experimental atherosclerosis. Baumann and Rusch⁵ also observed that choline did not influence the cholesterol content of the blood in cholesterol-fed rabbits. Zinnitz⁶ found that small amounts of cholesterol acetate inhibited the action of acetylcholine.

During the routine treatment of patients with acetyl- β -methylcholine chloride by iontophoresis, it appeared that a study of the serum cholesterol levels before and after treatment might be of interest. Accordingly, 12 persons were selected; 2 received 0.125 per cent acetyl- β -methylcholine chloride by iontophoresis and the remaining 10, 1 per cent of the drug by the same route. Serum cholesterol determinations were done before and at intervals of one-half, one, and two hours after the administration of the drug. Since the effect of the acetyl- β -methylcholine chloride occurs within a few minutes and persists for several hours, it was felt that the time intervals selected were of sufficient duration to demonstrate an effect, if any. Cholesterol determinations were done in duplicate by a modified Bloor's method.^{7, 8}

RESULTS

Of the 2 persons receiving 0.125 per cent acetyl- β -methylcholine chloride, one showed an appreciable drop in serum cholesterol in one-half hour, with a marked rise in the one- and two-hour specimens, while the other showed a slight rise from the control value. Five of the ten persons receiving the 1 per cent solution showed an appreciable rise in serum cholesterol, varying from 11 to 27 mg. above the control levels at the end of the two-hour period. Of the remaining 5, 2 showed no change, while 3 showed a slight fall in blood cholesterol. The serum cholesterol in the 12 persons studied varied by an average standard deviation of ± 5.1 per cent, with a range of ± 1.9 to ± 9.7 (Table I).

DISCUSSION

That acetyl- β -methylcholine chloride exerts a physiologic action when given by iontophoresis has been amply demonstrated by Kovacs, Saylor, and Wright,⁹ and by Kotkis and others.¹⁰ These workers have demonstrated that the cations of acetyl- β -methylcholine chloride were responsible for the physiologic reaction due to this compound and that they could be driven into the body by iontophoresis only from the positive electrode of a galvanic source.

Although rises and falls occurred in serum cholesterol following acetyl- β -methylcholine chloride iontophoresis, on analysis these variations were found to lack statistical significance. Bruger and Somaeh,¹¹ reporting on the diurnal variations in blood cholesterol in a group of 18 normal persons, found the average standard deviation to be ± 5.0 per cent for a twenty-four-hour period, with an average ± 3.5 per cent standard deviation in the morning hours. Since the present experiments were carried out during the morning hours, the average standard deviation of ± 5.1 per cent found in this series was only slightly higher than the ± 3.5 per cent reported by Bruger and Somaeh.¹¹

CONCLUSIONS

The administration of acetyl- β -methylcholine chloride by iontophoresis is accompanied by variations of the blood cholesterol, which, however, are not significant from a statistical standpoint.

THE DISTRIBUTION OF DOSES OF RADIOACTIVE PHOSPHORUS IN RODENTS*

SHIELDS WARREN, M.D., AND R. F. COWING
BOSTON, MASS.

WITH growing interest in the therapeutic uses of temporarily radioactive substances, it is important to learn the distribution of these in tissue and their rate of excretion. Radioactive phosphorus prepared† at the Harvard cyclotron by bombardment of red phosphorus was injected intravenously or intraperitoneally in mice, rats, and rabbits as aqueous solution of disodium acid phosphate. The dosages of radioactive material injected ranged from 5 microcuries to 17.5 microcuries in the mouse, from 30 microcuries to 239 microcuries in the rat, and from 50 microcuries to 84 microcuries in the rabbit.

Measurements were made by a Lauritsen type electroscop. The accuracy of measurements hinges on (a) the rate of deflection of the fiber on any given portion of the scale, and (b) the human error in determining the exact positions of the fiber in relation to the scale markings. This last error increases as the rate of deflection decreases. Hence values obtained for relatively active samples are more accurate than are those for samples of very low activity. The thickness of the aluminum foil window is of importance in the determinations. Ours is 0.0055 mm. thick, permitting passage of about 75 per cent of the soft β radiation of uranium oxide. The sensitivity of this electroscop is two divisions per minute per millicurie of radiation at one meter distance. We do not regard as accurate our measurements below 0.01 microcurie, although phosphorus of this degree of radioactivity may be detected in amounts of 3.5×10^{-14} Gm. About 10 per cent error must be allowed in all results by this method of measurement.

Although expressed in microcurie equivalents, the radiation is not actually comparable in biologic effect to the same amount of gamma radiation of radon. The tissue changes are now being studied.

TABLE IV
URINARY EXCRETION OF RADIOACTIVE PHOSPHORUS IN THE RAT

HOURS	PER CENT
3	6.1
6	6.3
21	5.6
30	3.5
45.5	2.9

In Tables I, II, III, and IV the amounts of radioactive phosphorus present in the tissues are calculated in per cent of the dose originally injected, corrected for rate of decay. In the case of larger tissues measurements were made of weighed aliquot portions; in the case of smaller organs the entire organ was weighed and used. Blood and urine were dried before measurement,* other tissues were compressed to a thin film and dried, or ground and then dried, or ashed.

As may be seen from Tables I to III, the per cent partition varies in the different animals. These values are only indicative of general trends, and vary

*The addition of varying amounts of urine up to fivefold, causing variation in thickness of the dry films, did not affect the accuracy of measurement.

somewhat with dosages given as well as other factors. Some absorption occurs within two hours after injection (Table I). The bone naturally picks up a large amount and retains it long, traces being present in the rabbit after 108 days. Owing probably to their excretory activity, the kidneys retained a trace at the same time, although none could be found in the liver (Table II).

The partition varies in the different species, but in general the spleen, liver, kidneys, and bone show a material degree of absorption and retention. In view of the distribution of leucemic lesions, this partition is serviceable in concentrating radioactivity to some degree in the tissues often affected by leucemic infiltration.

Urinary excretion is rapid. Hevesy³ found when tracer quantities of radioactive sodium phosphate are given by mouth, traces appear in the urine in twenty minutes. This urinary excretion is more marked early and falls off rapidly. About one-quarter the dose is excreted in the first forty-eight hours. Minute amounts were found in the urine of a rat ninety-eight days after subcutaneous injection.³

Table IV gives the rate of urinary excretion of radioactive phosphorus administered intraperitoneally or intravenously. In the first three hours, 6 per cent is excreted, and this rate continues with only slight diminution for twenty-one hours, falling to about one-half in the next day.

The fecal excretion could not be accurately measured in our animals, as slight contamination with urine could not be prevented. Tuttle, Scott, and Lawrence⁴ found from 13 per cent to 26 per cent of orally administered radioactive phosphorus in the feces of leucemic patients. An unknown amount of this represents failure of absorption from the gastrointestinal tract.

There is variation in the per cent partition in various tissues, to a minor degree among individual animals of the same species and to a greater degree between different species.

THE ESTER-HYDROLYZING ACTIVITY OF THE CENTRAL NERVOUS SYSTEM*

DAVID J. COHN, PH.D., IRVING KAPLAN, PH.D., AND MARTHA JANOTA, M.S.
CHICAGO, ILL.

INTRODUCTION

LIPIDS such as cephalin, sphingomyelin, lecithin, cholesterol, and related compounds form a major portion of nervous tissue. In the human brain and spinal cord, for example, fatty materials constitute about 50 per cent of the dry weight of the tissue,^{1, 2} as compared with 15 per cent in muscle tissue.³ It follows that lipid metabolism is of profound interest in the study of the biochemical processes that take place in the brain and nerves. Marked changes are known to occur in the compounds composing the myelin sheaths, especially during nerve formation and degeneration.^{1, 4}

Naturally, lipolytic and ester-splitting enzymes may be expected to play an important part in the formation and transformation of nerve tissue lipids. Bearing out this deduction is the increase in lipolytic enzyme activity of the cerebrospinal fluid found in conditions in which severe brain tissue destruction is known to occur.⁵

Despite the fact that lipolytic enzymes may thus be expected to be present in nervous tissue in considerable amounts, earlier workers did not find appreciable lipolytic activity.⁶⁻¹⁰ We surmised that this was due to the use of tissue extracts or autolysates. In the first instance they missed the desmoenzymes firmly attached to cellular structures; in the second, part of the enzymes were inactivated during autolysis.¹¹ We, therefore, used minced brain tissue carefully guarded against autolysis. By this technique we have been able to demonstrate marked lipolytic activity.

In this report we are presenting the results of quantitative estimations of the ester-splitting activity of various portions of the brain and spinal cord. This "enzyme map" of nervous tissue is of itself interesting in that the lipolytic activity has been found to vary with the anatomic structures and possibly, in turn, with the functions of the tissue. However, the main function of these normal distribution studies is to provide a standard of comparison for studies of diseased nervous tissue which are in progress.

METHODS

Preparation of the Tissue.—Throughout the experiments the brain and spinal cord of the monkey, *Macaca mulatta*, were used.† The monkeys had died of either

*From the Department of Chemistry, Michael Reese Hospital, Chicago.

Received for publication, July 5, 1940.

†We wish to thank Mr. Albert Milzer of the Samuel Deutch Serum Center for generously supplying the brains and cords of the monkeys.

pneumonia or tuberculosis so that they were not, strictly speaking, normal animals. However, the brains and cords appeared normal on gross dissection. In doubtful cases microscopic sections were made, but in no cases were abnormalities found. As soon as possible after death the brain and cord were removed and washed in a stream of distilled water to remove blood adhering to the surface. After stripping the leptomeninges, the cerebrum and cerebellum were separated from the pons and medulla oblongata. The following tissues were removed as carefully and completely as possible: cerebral cortex, centrum semiovale, corpus callosum, thalamus, and gray tissue of the caudate and lenticular nuclei. A slice of cerebral tissue (mixed cerebrum) containing cortex and subcortical white matter was also removed. No attempt was made to separate gray and white matter of the cerebellum, pons, or medulla, since the small size of the monkey brain made this impractical. In this study the pons and medulla, which were always combined, are referred to as the brain stem.

The tissues were minced separately in Petri dishes with a scalpel and spatula, formed into oblong cakes, and kept in the refrigerator at 0° to 5° C. Precautions were taken to minimize the length of time during which any tissue was exposed to room temperature. Tissue prepared in this way could be kept for a week or more with no significant loss of lipolytic activity.

Determination of the Lipolytic Activity.—The lipolytic activity was determined as follows: Substrate emulsions of tributyrin, ethyl butyrate, or olive oil, were prepared by shaking one part of substrate with 4 parts of 5 per cent gum acacia solution. The hydrolysis mixtures, made up in 50 c.c. Erlenmeyer flasks, preferably glass stoppered, contained 2 c.c. of substrate emulsion, 1 c.c. or more of buffer solution, and enough distilled water to bring the volume to 10 c.c. The amount and concentration of the buffer solution depend on the purpose of the experiment. A piece of tissue cut from the previously described cake and estimated to weigh between 250 and 300 mg. was used as the enzymic material. The exact moist weight of tissue was formed by weighing the hydrolysis flask before and after addition of the tissue. The flask was shaken vigorously by hand until the tissue was distributed in small pieces through the emulsion, and then incubated for twenty-four hours at 37° C. At the end of this period the reaction was stopped by the addition of 10 c.c. of 95 per cent alcohol, and the amount of acid formed was determined by titration with 0.05 normal sodium hydroxide, using 10 drops of 1 per cent phenolphthalein as indicator. Two kinds of control determinations were used. A substrate blank was determined by titrating a hydrolysis mixture after incubation without brain tissue. A tissue blank was determined by incubating tissue with buffer and water without substrating and titrating as previously the lipolytic activity was calculated as follows:

(1) Lipolytic activity per gram of tissue

$$= \left[\frac{\begin{array}{cc} \text{(c.c. 0.05 N NaOH)} & \text{—(c.c. 0.05 N NaOH)} \\ \text{Tissue and buffered} & \text{Buffered} \\ \text{substrate} & \text{substrate} \end{array}}{\text{(weight of tissue used, in milligrams)}} \right] \times 1000$$

—Autolysis value per gram of tissue.

The "autolysis value" in the foregoing formula was obtained as follows:

(2) Autolysis value per gram of tissue

$$= \left[\frac{(\text{c.c. of 0.5 N NaOH}) - (\text{c.c. 0.05 N NaOH})}{\frac{\text{Tissue and buffer}}{(\text{weight of tissue used, in milligrams})} \times \frac{\text{Buffer}}{1}} \right] \times 1000$$

Throughout the course of the experiments the phosphate buffer of Sørensen, as modified by Hastings and Sendroy,¹² was used. In order to avoid the arbitrariness involved in the use of a single buffer concentration, we studied the lipolytic activity at various concentrations of phosphate buffer. A stock solution of buffer of pH 7.9 was prepared at a salt concentration of 0.2 molar. By using 1, 2.5, 4, 5, or 8 c.c. of this stock solution in hydrolysis mixtures whose total volume was 10 c.c., it was possible to obtain phosphate buffer concentrations of 0.02, 0.05, 0.08, 0.10, and 0.16 molar, respectively. To obtain a buffer concentration of 0.0067 molar, 1 c.c. of fifteenth-molar stock solution was used. The activity was determined at pH 7.9 because this pH value is in the neighborhood of maximum hydrolysis of tributyrin and ethyl butyrate. Experiments were also made at the more physiologic pH value of 7.4. The difference in pH exerted no significant influence on the results obtained.

In all, 13 monkeys were used in the experiments reported. In view of the fact that the results obtained with individual animals showed relatively small variations, this number was considered sufficient.

RESULTS

All portions of nervous tissue tested showed considerable tributyrin and ethyl butyrate-splitting activity. This activity per gram of material was of the order of ten times that of blood serum. Neutral fat (olive oil) was not appreciably hydrolyzed.

The concentration of phosphate buffer in the hydrolysis mixture affected the rate and extent of hydrolysis. Within certain limits increased phosphate buffer concentration was accompanied by increased hydrolysis. In the case of ethyl butyrate this increase reached a maximum at 0.02 to 0.05 molar phosphate buffer concentration. Tributyrin-splitting activity reached a maximum at 0.16 molar.

Although the absolute ester-splitting power, as represented by the titration values in Table I and Figs. 1 and 2, varied from animal to animal, the relative order in which tissues from each individual animal split each ester was always the same. In other words, the ester-splitting power of the different tissues was characteristic of the tissues; the relative hydrolyzing power of various tissues under similar conditions of hydrogen-ion concentration, temperature, and phosphate buffer concentration was always the same. Thus at 0.16 molar phosphate buffer concentration the various tissues studied hydrolyzed tributyrin in the following order: cerebral cortex, mixed cerebrum, striatal gray matter, thalamus, cerebellum, stem, spinal cord, and white matter (Fig. 1). At lower phosphate buffer concentrations the difference in the tributyrin-splitting activity of the several tissues was not quite so distinct, yet gray and mixed tissues always showed more tributyrin-splitting activity than spinal cord and white matter,

0.0067 Molar Phosphate Buffer									
Tributyrin	Max.	14.9	15.7	17.1	17.3	16.0	16.3	13.2	14.6
	Min.	13.2	11.6	13.2	12.6	12.2	13.9	10.8	10.9
	Avg.	14.4	14.0	14.7	14.1	14.4	15.2	12.3	11.9
Ethyl butyrate	Max.	9.1	11.3	9.3	10.2	9.8	7.1	6.0	7.6
	Min.	6.6	6.9	5.6	7.0	4.5	5.7	3.0	3.4
	Avg.	8.2	8.6	7.3	7.9	6.5	6.5	4.4	5.3

Ester-splitting power of nervous tissue is strongest in gray matter. Phosphate buffer concentration has a notable effect.

On the other hand, ethyl butyrate-splitting activity at all phosphate concentrations remained in the order: cerebral cortex, mixed cerebrum, striatal gray matter, thalamus, stem, cerebellum, white matter, and spinal cord (Fig. 2).

It will be noted that the order of ethyl butyrate-splitting activity is somewhat different from that for tributyrin-splitting activity. The stem is more active than the cerebellum with respect to ethyl butyrate, and white matter is more active than spinal cord tissue. These differences were found consistently in all the animals studied.

DISCUSSION

It has been found in the present work that all the various tissues of the brain and spinal cord which we have studied have marked ester-splitting ability. The quantitative measure of this ester-splitting activity varies throughout the central nervous system and is a chemical characteristic of each tissue portion. In general, the ester-splitting activity is greatest in gray matter, least in white matter, and intermediate in mixed tissues.

The presence of lipolytic enzymes in the brain and spinal cord raises the question of the source and functions of these enzymes. Since white matter consists of nerve fibers and neuroglial cells, the enzymes of white matter are probably derived from the latter. Whether or not astrocytes, oligodendroglia, and microglia, contribute equally to the enzymatic activity of the white matter, is a question which cannot at present be settled. It is thought, on anatomic grounds,¹³ that the oligodendroglia are related to the formation and maintenance

On the other hand, ethyl butyrate-splitting activity at all phosphate concentrations remained in the order: cerebral cortex, mixed cerebrum, striatal gray matter, thalamus, stem, cerebellum, white matter, and spinal cord (Fig. 2).

It will be noted that the order of ethyl butyrate-splitting activity is somewhat different from that for tributyrin-splitting activity. The stem is more active than the cerebellum with respect to ethyl butyrate, and white matter is more active than spinal cord tissue. These differences were found consistently in all the animals studied.

DISCUSSION

It has been found in the present work that all the various tissues of the brain and spinal cord which we have studied have marked ester-splitting ability. The quantitative measure of this ester-splitting activity varies throughout the central nervous system and is a chemical characteristic of each tissue portion. In general, the ester-splitting activity is greatest in gray matter, least in white matter, and intermediate in mixed tissues.

The presence of lipolytic enzymes in the brain and spinal cord raises the question of the source and functions of these enzymes. Since white matter consists of nerve fibers and neuroglial cells, the enzymes of white matter are probably derived from the latter. Whether or not astrocytes, oligodendroglia, and microglia, contribute equally to the enzymatic activity of the white matter, is a question which cannot at present be settled. It is thought, on anatomical grounds,¹³ that the oligodendroglia are related to the formation and maintenance

matter, such as thalamus and cerebellum, were more active than mixed tissues rich in white matter, such as stem and spinal cord.

4. The ethyl butyrate-splitting activity was greatest in the cerebral cortex and least in the spinal cord. The cerebellum has less activity than other mixed tissues including the stem. White matter was less active than gray or mixed tissues with the exception of the spinal cord.

LABORATORY METHODS

GENERAL

A NOTE ON THE BACTERIOLOGIC CULTURE OF BONE MARROW IN TYPHOID FEVER*

MILTON S. SACKS, M.D.,† AND FRANK W. HACHTEL, M.D.
BALTIMORE, MD.

THE localization of bacilli in the bone marrow during an attack of typhoid fever has been known for many years. Lougcope¹ in 1905 noted the presence of large numbers of characteristic macrophages here, as well as in the Peyer's patches of the intestines, and also observed areas of necrosis in the marrow similar to those of the spleen and lymph nodes. Ludke² reported the persistence of typhoid bacilli in the lymph nodes and bone marrow of guinea pigs following intravenous inoculation and their proliferation in these situations after disappearance from the blood. Gay³ further noted that the organisms were present in the marrow of infected rabbits not only after disappearance from the blood, but also from the lymph nodes and spleen. The clinical significance of this localization has been stressed in regard to the resultant leucopenia and neutropenia occurring during the acute phase of the disease and the osseous lesions which occasionally occur as sequelae of the infection. However, the value of marrow culture during the disease has been pointed out only within the past several years. In this communication we wish to record our experience with the bacteriologic examination of the marrow in three cases of typhoid and to comment briefly on the usefulness of this procedure.

Culture of the bone marrow *in vivo* has been closely associated with the increasing interest and exploitation of bone marrow biopsy in the blood dyscrasias. Cytologic examinations of the marrow have increased in number as a result of the introduction of simpler and more practical methods of securing samples of this tissue. Among the earliest attempts at marrow biopsy were those of Ghedini,⁴ who first advocated tibial trephination for the diagnosis of leishmaniasis. This technique never became widely popular, although it was used by Zadek⁵ and Peabody⁶ in 1922 and 1927, respectively, in their classical studies on the marrow changes in pernicious anemia. Sternal trephination, introduced by Seyfarth⁷ in 1923, reawakened interest in the diagnostic value of marrow biopsy. But it remained for the introduction of needle puncture of the sternum by Arinkin⁸ in 1929 to popularize marrow study.

Within the past several years reports of attempts at bacteriologic and parasitologic examination of marrow in a variety of infections have appeared.

Received for publication, March 22, 1940.

largely in European literature. Among the diseases so studied have been typhoid fever, brucellosis, subacute bacterial endocarditis, miliary tuberculosis, malaria, leishmaniasis, trypanosomiasis, and various septic states due to members of the pyrogenic group of bacteria. Marrow examination in leishmaniasis seems to be accepted as a diagnostic procedure of recognized value.⁹ In malaria Osgood¹⁰ has reported the occurrence of larger numbers of parasites in the marrow than in the peripheral blood. Bock¹¹ concluded from a comparative study of arterial and venous blood cultures with marrow culture in a variety of septic states that the latter, while inferior to arterial culture, was considerably easier to obtain and was apparently superior to the more commonly used venous blood culture. Favorable experiences with this method in the diagnosis of brucellosis have been reported by Signorelli¹² and Baserga and Barbagallo.¹³

Fig. 1.
(Courtesy of Topley and Wilson)

The earliest report of bacteriologic culture of bone marrow biopsy material in typhoid fever is contained in the little-known paper of Gerbasi,¹⁴ who in 1925 obtained positive results from tibial bone marrow in thirteen cases. No further reports occurred until 1935, when Debré and co-workers¹⁵ cultured the marrow obtained by sternal puncture in ten cases of typhoid during the first and second weeks of infection and obtained positive results in all instances. Further studies are recorded by Storti and Filippi,¹⁶ Baserga and Barbagallo, and others. In all, approximately two hundred cases are included in these reports. Positive cultures were apparently obtained from patients not only in the first few days of the disease, but also as late as sixty to sixty-five days following the onset. It would appear from a scrutiny of this material that typhoid bacilli are present over a longer period of time in the marrow than in any other situation and that this tissue offers a constant reservoir from which positive cultures may be obtained.

The aim of diagnosis in typhoid fever has always been the actual isolation and identification of the organism from any possible source. The most fruitful sources for culture in active cases have been the blood and feces. Determination of the agglutinin content of the serum is an indirect method of diagnosis, the reliability of which depends on the demonstration of progressive increase in titer. Frequently titers of sufficient strength to be diagnostic do not develop before the end of the second week of the illness. Moreover, in this day of increasingly widespread use of prophylactic vaccination, the possibility of an "anamnesic reaction" of typhoid agglutinins to nonspecific hyperpyrexia must always be considered. Reference to Fig. 1 demonstrates that during the latter part of the second week of illness the diagnostic efficiency of current laboratory measures averages about 70 per cent. During this time, which has been called the "mute period" by Baserga and Barbagallo, marrow culture appears to have its greatest diagnostic usefulness.

The technique followed in the cases to be cited was as follows: The skin area over the body of the sternum at the level of the third interspace was cleaned with iodine and alcohol, and then anesthetized with 2 per cent novocain down to and including the periosteum. The needle used for puncturing the sternum was No. 18 gauge lumbar puncture needle with stylet in place, shortened to approximately 5 cm. according to the method suggested by Young and Osgood.¹² It was introduced at an angle of approximately 70°, and with a steady downward and somewhat rotatory pressure the anterior cortex was readily penetrated. After withdrawing the stylet, a tightly fitting 10 c.c. syringe was used to aspirate approximately 4 c.c. of sanguineous "marrow juice." This was transferred to media and treated in a manner similar to blood culture material. Most satisfactory growth was obtained on media containing selenite F.

Three patients with typhoid fever admitted to the University Hospital during August, September, and October, 1939, afforded an opportunity to observe the value of this procedure. Sternal marrow cultures were obtained once in each instance, i.e., on the fourteenth, nineteenth, and twenty-first days of the illness, respectively. Data concerning other bacteriologic and serologic studies in these cases, together with brief abstracts of the case histories, are cited.

CASE 1.—W. E. (Chart No. 27343), a white male, aged 14 years, was admitted to the Medical Service at the University Hospital on September 12, 1939, complaining of weakness, loss of appetite, and fever of two weeks' duration. Further questioning elicited complaints of more or less constant headache, marked constipation, and pain in the abdomen. The patient told of swimming in the harbor on several occasions some days prior to onset of illness. Examination revealed a very toxic, somewhat lethargic boy, with an admission temperature of 101.4° F. and a pulse rate of 88 per minute. Scattered small erythematous papules, which faded on pressure, were observed over the chest, back, and abdomen. A few sonorous and wheezing râles were heard over the bases of both lungs. The tip of the spleen was palpable 4 cm. below the left costal margin and the edge of the liver was likewise felt.

Aside from cellulitis of the right thigh which subsided uneventfully, the patient's course was entirely typical for typhoid fever, with persistence of hyperpyrexia for three weeks and gradual return to normal by lysis. Bone marrow culture on the twenty-first day of the illness was positive, and a simultaneous blood culture was negative. Agglutination

titer, with both O and H antigens, never rose above 1:160. In this instance, the diagnosis having been established by prior positive cultures, bone marrow culture was merely of academic interest.

CASE 2.—A. F. (Chart No. 26969), a white female, aged 11 years, was admitted to the University Hospital on August 26, 1939, complaining of malaise and feverishness of thirteen days' duration. Illness was insidious in onset, with progressive drowsiness, fever, frequent headaches, and anorexia. Examination revealed a well-nourished, well-developed, somewhat toxic young girl, whose admission temperature was 105° F. and whose pulse rate was 110 per minute. Numerous "rose spots" were seen on the back, arms, and abdomen. A harsh mitral systolic murmur was heard. The spleen was not palpable.

	69th					1:320 ++

All bacteriologic examinations remained negative until August 31, when both bone marrow and urine cultures were found to contain *E. typhosa*. The agglutinin titer, however, two days after admission was positive up to a dilution of 1:320. Thus, in this instance, the

first definite bacteriologic evidence of typhoid fever was a positive marrow culture on the nineteenth day of illness. The patient's course in the hospital was marked by subsidence of fever within a week after admission, only to be followed a few days later by recurrence of hyperpyrexia, associated this time with several positive blood cultures. Recovery, however, was essentially uneventful, and the patient was discharged on October 22, 1939.

CASE 3.—D. R. (Chart No. 27929), a white female, aged 14 years, was admitted to the University Hospital on October 7, 1939, complaining of malaise, fever, and listlessness which began on September 28. The illness was characterized by sudden onset with a chill followed by elevation of temperature to 104° F. On succeeding days there was recurrence of chills. On October 1, following therapy with quinine, there occurred a generalized wheallike eruption which lasted for twenty-four hours. Because of a known case of typhoid in the vicinity and continued hyperpyrexia, hospitalization was advised. Examination on admission showed a well-developed, well-nourished white female of 14 years, lying quietly in bed. The temperature was 100° F. and the pulse rate was 80 per minute. The remainder of the physical examination at this time was essentially negative. The laboratory studies were likewise noncontributory. Agglutination studies for typhoid were positive only up to titer of 1:80. Four days after admission, i.e., on the fourteenth day of illness, bone marrow culture was reported positive for *E. typhosa*. This was the first definite bacteriologic evidence of the etiology of the hyperpyrexia. It will be observed that blood cultures remained persistently negative in this case.

COMMENT

The rationale for the bacteriologic examination of bone marrow exists in the fact that in this situation one may possibly secure capillary (arterial) blood as well as material rich in phagocytic reticulo-endothelial cells. These factors together are believed to offer greater probability of obtaining positive results than culture of venous blood taken at a distance from the locus of infection. In typhoid fever the growth and proliferation of organisms in the marrow has been known for many years. However, it remained for the development of a relatively simple technique, i.e., sternal puncture, to stimulate the clinical exploitation of this source of bacteria. The limited number of our cases does not permit at this time any broad generalizations as to the comparative value of this diagnostic procedure. However, our experience, as well as a consideration of the recent literature, seems to suggest that culture of the marrow offers a reliable and constant source of organisms during the acute disease from the earliest

days of the illness to the end of the febrile period. The procedure is, therefore, of value in early diagnosis, but appears to have its greatest usefulness at a time, roughly between the tenth and fifteenth days of the disease, when current diagnostic laboratory procedures are positive in only about 70 per cent of the instances. The further value of this technique, moreover, appears to us to lie in its possible extension to other types of infection associated at one time or another with bactericemia.

SUMMARY

1. Bacteriologic culture of sternal marrow obtained by needle puncture on the fourteenth, nineteenth, and twenty-first days of the illness in three cases of typhoid fever was uniformly positive.

2. Further work seems indicated to establish the value of this procedure in typhoid fever and other infections.

IMMUNOLOGIC TEST FOR HUMAN BLOOD AND HUMAN PROTEIN IN STOOLS*

LUDWIG PINCUSSEN, M.D., PH.D., CHICAGO, ILL.

IT IS well known that protein is generally absent in human stools but that there are occasional cases in which presence of protein may be shown by chemical methods.

It is of the greatest importance to determine whether such protein found in the stool is derived from food not sufficiently digested or from the human body because of the vastly different significance of these findings. Hence it seems of practical value to have a readily available method by means of which protein in the stool can be easily identified as being derived from the human body.

Since we have no special chemical test for human blood protein, we must make use of immunochemistry. Injecting human serum into rabbits, the antiserum developed after a certain length of time will react in a specific way, giving a specific precipitate with human serum protein.

To prepare this antiserum (precipitin), human serum free of hemoglobin is diluted ten times with saline and after being slightly acidified (to pH 6.5) is absorbed on the same volume of aluminum cream following the procedure of Hektoen and Welker. After centrifuging until no protein is left in the supernatant fluid, the fluid is discarded and the remaining precipitate is mixed with saline so that 1 c.c. of this emulsion corresponds to 3 c.c. of diluted or 0.3 c.c. of original serum. Twenty cubic centimeters of this emulsion are injected at different places in the muscles of the hind legs of a rabbit forming a few deposits from which the protein may be absorbed into the blood. The antibody has usually reached a maximum at the end of two weeks. After a test has shown a titer of 1:100,000 with human serum, the rabbit is bled to death and the serum is ready for the test. It is kept in the refrigerator for further use.

For the stool precipitin test the stool is well mixed so as to secure a thorough distribution of the protein in the stool. As it is rather difficult to secure a completely uniform stool mixture, several portions of the well-mixed stool may have to be examined. The stool specimen is thoroughly mixed with five parts of 0.9 per cent sodium chloride solution. The stool suspension is centrifuged, the supernatant fluid is filtered through good filter paper, and the filtrate is returned to the filter until the filtrate appears clear. Clearing the filtrate by use of adsorbents, such as kaolin or Fuller's earth, or by using a Berkefeld filter is not admissible, as by such procedure protein would be removed. As soon as the filtrate is clear it is ready for the test.

For the test we employ very small test tubes, 3 mm. in diameter and 1 inch high. Pipettes with very fine points are made from glass tubing. With one of

*From the Department of Physiological Chemistry and the Laboratory of Pharmacology and Therapeutics, University of Illinois College of Medicine.
Received for publication, March 22, 1940.

these pipettes we place in the tube a small amount of stool filtrate so that the tube is about one-third filled. With another fine pipette we lay about the same amount of antiserum below the stool filtrate, taking care that the point of the pipette goes through to the bottom of the tube. If human protein is present, a white ring—the specific precipitate—will develop at the border of the two layers. In case the protein content is rather high, the ring will appear immediately. If no ring appears within one hour, the test is negative.

The reaction is specific for human protein and is negative for protein from food or bacterial bodies. Hence if positive with stool extract, it is specific for colitis, exudates, or bleeding from the colon.

For differentiating between exudate and bleeding the absence or presence of human blood corpuscles must be determined. This can also be done immunologically, testing by the precipitation method for human hemoglobin.

To prepare an antiserum for human globin, rabbits are injected with a solution of human hemoglobin. This is prepared by hemolyzing thoroughly washed human corpuscles by adding slowly a small amount of ether (10 to 12 drops to 100 c.c.), shaking two to three minutes and repeating this procedure a few times until the corpuscles are completely hemolyzed. This solution is mixed with three parts of aluminum cream and centrifuged. The clear red solution devoid of serum protein and containing the hemoglobin may be used as an antigen for producing a precipitin specific for human globin. Injecting a rabbit every third day with increasing amounts of this solution, 1 c.c., 2 c.c., 3 c.c., 5 c.c., 8 c.c., and 10 c.c., one week after the last injection the serum may give the precipitin test with a hemoglobin solution 1:100,000. The test is made in the same way as described before for proving the presence of human protein. Positive test of the stool extract with this antiserum demonstrates the presence of human globin and thus of hemoglobin, and shows, together with the positive test for human blood protein, that bleeding occurred some place in the intestine.

CONCLUSIONS

1. By precipitin reaction, using as antibody a specific human serum-rabbit antiserum, the presence of human blood protein may be detected in human stools.
2. Using as antiserum a human hemoglobin-rabbit antiserum, the presence of human corpuscles or derivatives thereof can be demonstrated.
3. Positive precipitin reaction of stool extract with both serum antiserum and globin antiserum is characteristic for bleeding, whereas precipitin reaction with serum antiserum and negative test with globin antiserum will indicate an exudate from the bowels as produced by an exudative process.
4. Testing with dilutions of the feces extract will give a rough quantitative estimation.

ANTHRAX IN SHAVING BRUSHES*

R. V. STONE, F.A.P.H.A., LOS ANGELES, CALIF.

THE finding of anthrax spores in toothbrushes, hairbrushes, or shaving brushes occurs infrequently. Smyth (1939) reviews a twenty-year survey of anthrax in the United States.¹ In his tabulation of "Cases and Deaths by Source of Infection" appear 2,044 cases and 136 deaths where the source of infection is other than "transportation," "agricultural," or "professional." Such definite commercial commodity data have been adapted to Tables I and II.

TABLE I

ANTHRAX CASES AND DEATHS HAVING DEFINITE TRADE COMMODITY SOURCES OF INFECTION 1929-1938 INCLUSIVE

COMMERCIAL COMMODITY	CASES	DEATHS	TOTAL CASES (PER CENT)	TOTAL DEATHS (PER CENT)
Hides and skins	1,113	58	54+	43-
Wool	565	34	28-	25
Hairbrushes	207	18	10+	13+
Shaving brushes	159	26	8-	19+
Total	2,044	136 (7 -%)		

+ signifies slightly more than the whole number given.

- signifies slightly less than the whole number given.

TABLE II

COMPARISON OF COMMERCIAL COMMODITY SOURCES OF INFECTION WITH DEATHS REPORTED

COMMERCIAL COMMODITY	CASES	DEATHS	DEATHS TO CASES
Hides and skins	1,113	58	5+
Wool	565	34	6+
Hairbrushes	207	18	9-
Shaving brushes	159	26	16+

Tables I and II emphasize that, although shaving brushes represent slightly less than 8 per cent of this grouping of industrial cases, yet the highest percentages of deaths occur in the shaving brush source group. The higher vascularity of tissue exposed and the minute nicking of the epidermis during shaving both favor the introduction of the organism into a suitable environment for propagation.[†]

The isolation and identification of *Bacillus anthracis* are simple laboratory tasks. However, in the examination of suspected shaving and similar brush material, a "hunch" in our own experience seems worthy of reporting, as evidence of extending sampling a bit further than in the examination of the hair or bristles of the brush proper.

Smyth contends, "The latest outbreak of shaving brush cases is due to shipments of cheap brushes made from 'sterilized' horsehair, imported from Japan." We were interested in the possible presence of such brushes in our community.

*From the Public Health Laboratories, Los Angeles County Health Department, Los Angeles.²

Received for publication, April 1, 1940.

[†]Concerning shaving brushes, Smyth states, "They have a fatality rate of from 50 per cent to 60 per cent."

Early in 1939 our sanitary inspectors were asked to find out if "Imperial, Sterilized Japan, 332" shaving brushes were in stock for sale in our local stores. Only one such brush was found. It was purchased in a 5 and 10c store, by inspector W. C. Weymouth of our department. The brush was sealed well in cellophane, and was an attractive appearing piece of merchandise. Much to our surprise, this single sample yielded anthrax organisms by direct culture and from guinea pig inoculations. This brush was the only one of this brand found still unsold.

Radio and press requests were made in order to contact purchasers of this brand of brush. Nine used brushes were submitted to us as a result, one being received from a mountain town about 350 miles distant from Los Angeles.

These brushes had been in active use by the owners; none yielded anthrax organisms from the brush portion. Only one of the owners felt that he had experienced an "infection." This man stated that he had bought the brush about a year before. He "now recalled" that he had probably experienced an anthrax infection following the initial use of the brush. Our interested inquiry as to what kind of symptoms he experienced brought the reply of "no sores, but a peculiar feeling under the skin." We asked "What sort of peculiar feeling?" The answer was "Oh! like ants crawling around under the skin, you know, ant tracks!" Thus is our terminology sometimes misinterpreted by the layman.

We did not expect to recover anthrax from these used brushes, but examination of the merchandise led to an attempted innovation in such an examination.

The handles of hard wood were broken open, and the resinous brittle gum was crushed, liberating the ends of the hairs from their protective seal. The handle end of the hair was then subjected to culture and easy procedures. One of the nine yielded a luxuriant growth, and gave typical post-mortem evidence in a cavity; the heart-blood culture yielded pure colonies of anthrax.

Inasmuch as this brush had been purchased either late in 1937 or early in 1938 and had been in constant use up to March, 1939, it is interesting to conjecture on whether or not the actual brush tuft portion had been effectively sterilized after the handle and hair had been put together, or had the user simply been fortunate is not contracting anthrax during the period of first use, before the spores were removed as a result of the daily washing out of the brush?

SUMMARY

Breaking open the handles of bristle or hairbrushes, removal of the handle binder from the hairs, and subsection of this portion of the hair to cultural and animal procedures, for the demonstration of anthrax, yielded a positive result in one of nine used shaving brushes of Japanese manufacture.

LABORATORY STUDIES IN THE FALCIPARUM MALARIA OF DRUG ADDICTS*

HARRY MOST, M.D., AND MARGARET H. TEWKSBURY, M.D., NEW YORK, N. Y.

THE literature contains many clinical pathologic studies concerning the disease of malaria. The recorded observations deal with the various types of malaria resulting from natural mosquito infection, and more recently, from the malaria induced for the therapy of nervous system syphilis. Except for the notes on "Laboratory findings" contained in Helpern's paper,¹ we have been unable to find any clinical pathologic studies of the falciparum malaria of drug addicts resulting from the common use of hypodermic syringes for intravenous heroin administration.

Falciparum malaria in drug addicts is now a well-established and recognized entity in New York City and probably also occurs in considerable numbers in other large metropolitan areas. Studies on the epidemiology and clinical aspects of the disease are reported elsewhere.²

During the past six years we have had the opportunity of observing well over two hundred drug addicts suffering from falciparum malaria contracted as a result of the common use of hypodermic syringes for intravenous heroin administration. All clinical varieties of falciparum malaria were encountered, including fatal cerebral, gastrointestinal, and hemoglobinuric syndromes. In many cases detailed laboratory studies were carried out. It is the object of this paper to present the findings of these studies.

MATERIAL AND METHODS

The patients studied in this series were drug addicts in whom a proved diagnosis of falciparum malaria was made. They were hospitalized, observed, and treated on the wards of the Third Medical Division and the Medical Service of the Psychiatric Division of Bellevue Hospital, New York.

Blood counting was done with the aid of certified blood pipettes. Hemoglobin was determined by an acid hematin method using a Klett-Newcomer discolorimeter. The mean corpuscular volume was determined by the Wintrob method.

The nonprotein nitrogen was done by the micro-Kjeldahl method, and blood sugar by the Folin-Wu method; serum bilirubin by the Ernst-Förster method and plasma proteins by the tyrosine method. The protein in the spinal fluid was precipitated and determined by the micro-Kjeldahl method.

Urobilinogen was determined by the dilution method of Wallace and Diamond using Ehrlich's reagent (paradimethylaminobenzaldehyde).

*From the Departments of Medicine and Clinical Pathology, New York University College of Medicine; and the Third Medical Division and the Medical Service of the Psychiatric Division of Bellevue Hospital, New York.

Received for publication, April 19, 1940.

HEMATOLOGIC OBSERVATIONS

Red Blood Cells, Hemoglobin, and Mean Corpuscular Volume.—In the hematologic tables one sees that in about half the individuals studied, considerable anemia existed. In 28 per cent the red blood cell count ranged between 1 and 2.9 million cells per cubic millimeter and in 46 per cent the hemoglobin was reduced below 10 Gm. per 100 c.c. On the other hand, in many individuals, despite severe malarial infection, little or no anemia existed.

The mean corpuscular volume was determined in 24 patients. The results obtained in 15 showed that the size of the red blood cells is in the normal range. In 9 patients, however, there was definite macrocytosis. Since there is no corpuscular enlargement associated with the development of *P. falciparum*, another explanation must be sought for the macrocytosis. Certainly these cases are complicated by dietary insufficiency and possibly by liver damage. These factors may account for the phenomenon of macrocytic anemia. It is of interest to note that Fairley and Bromfield,³ in studying the average diameter of the red blood cells in 14 patients with *P. falciparum* infection (not drug addicts) by the balometer, found them all within the normal range. He doubts the existence of true megalocytic anemia in uncomplicated cases. Certainly the disease in the drug addict is not simple, uncomplicated malaria. Prolonged dietary inadequacy associated with chronic drug addiction, in many cases alcoholism and intrinsic

or malarial liver disease, may constitute factors in the mechanism of the anemia seen in these addicts, in addition to that directly dependent on the malarial infection itself.

White Blood Cell Count and Monocytosis.—From a diagnostic point of view, the white blood cell count and the differential formula, especially with reference to the number of monocytes, is seen to be of little value. In our series the white blood cell count was found elevated in 31 cases, normal in 35 cases, and less than normal in 9 cases. Monocytosis was seen only in 12 of 75 cases in which a differential count was done. Unfortunately this finding, so much stressed in texts, would appear to be of little value as a diagnostic aid. The presence of ingested pigment, however, is strong presumptive evidence of malarial infection.

BLOOD CHEMICAL OBSERVATIONS

Nonprotein Nitrogen.—The blood urea is frequently elevated in falciparum malaria. The nonprotein nitrogen was determined in 62 patients. Values between 51 and 100 milligrams per cent were found in 8. In two of these patients kidney disease (acute or chronic glomerulonephritis) was known to exist, but in the remaining 6 the elevation was felt to be associated with the malarial process and was dependent on one or more of the following: dehydration, vomiting, anoxemia, anemia, and hemoconcentration. In the cases in which recovery followed treatment, but no kidney disease existed, the values returned to normal very quickly.

Blood Sugar.—The blood sugar was found elevated above 150 milligrams per cent in 6 patients. In these one or more of the following was present: severe vomiting, hemoconcentration, high fever, anemia, or impaired liver function. We feel that one or more of these factors in our series may explain temporary derangement of the carbohydrate regulatory mechanism.

Serum Bilirubin.—Values of serum bilirubin up to 1.0 milligram per cent were considered normal. Sixty-six per cent of the persons studied exhibited hyperbilirubinemia. In the cases in this series, whenever the height of the serum bilirubin was considerable, the van den Bergh reaction was of the direct immediate type. The higher levels were associated also with moderate anemia and clinical icterus, as well as with urobilinuria.

Plasma Proteins.—The total proteins were reduced below 6.0 Gm. per cent in 11 of 19 individuals whose plasma proteins were studied. In the main this reduction, as well as a lowering or inversion of the albumin-globulin ratio, was due to the depression in the value for serum albumin. The latter values were considerably below normal in at least 16 of the total number studied. Values for the serum globulin, on the other hand, were essentially normal, although definitely increased in 6 patients.

SPINAL FLUID

It is surprising that in the face of the severe involvement of the brain, which occurred so often, relatively few changes were observed in the composition of the spinal fluid.

SEROLOGIC DATA

The Wassermann reaction was strongly positive (4 plus) in 15 patients, weakly positive in 2 and doubtful in 3. Even though one may concede a greater incidence of syphilis among drug addicts, one would hardly expect such a high percentage of syphilis if the positive Wassermann is interpreted as evidence of syphilitic infection. In 8 persons in whom the Wassermann was 4 plus at the height of the malaria, the reaction was negative after recovery. Two weakly positive and two doubtful reactions likewise became negative after recovery from active malaria. That the Wassermann reaction in malaria may be positive in the absence of syphilis is well appreciated in the tropics and elsewhere⁴ and is re-emphasized in this series.

Henry's Serum Flocculation Test for Malaria (Chorine Modification).⁵—This test was positive in the 25 patients in whom it was carried out. We performed it only as a matter of academic interest, since in all cases the diagnosis

was established previously by an examination of a stained blood smear. The test may be of value if plasmodia cannot be found, as in latent or chronic or unusual forms of malaria.

URINARY FINDINGS

The urinary findings were not striking. Albumin, acetone, bile, reducing substance, and methemoglobin were present in small amounts, and red blood cells and casts in small numbers. Any or all of the findings enumerated in Table V may be explained by the malarial infection per se. On the other hand, cerebral involvement, vomiting, starvation, dehydration, diarrhea, ingestion of other drugs, hemorrhage, and intravascular hemolysis, which operated in many cases in this series, might equally serve to explain the urinary findings here reported. The output of urinary urobilinogen is also represented in Table V. It is of note that in 46 persons values of 1:40 dilution or higher were found. Hemoglobinuria appeared in the two patients with clinical blackwater fever.

SUMMARY

The clinical pathology of falciparum malaria of drug addicts is presented. None of the laboratory findings, other than direct blood smear examination, is diagnostic of the disease. On the whole, the laboratory observations are those seen in natural and induced malaria. The outstanding findings are:

1. Anemia, which may be macrocytic.
2. Hyperbilirubinemia with an altered van den Bergh reaction.
3. Hypoproteinemia, due on the whole to depression in the value of the serum albumin and resulting frequently in reduction or inversion of the albumin-globulin ratio. The serum globulin may be considerably elevated.
4. Relatively high incidence of positive Wassermann reactions.
5. Positive Henry's flocculation test.
6. Increased urinary output of urobilinogen.

A COTTON-PLUG WRAPPING MACHINE FOR BACTERIOLOGIC CULTURE TUBES AND BOTTLES

L. L. KEMPE AND H. R. SHIPMAN,* MINNEAPOLIS, MINN.

IN MANY bacteriologic laboratories large numbers of cotton plugs are required for use as stoppers in culture tubes, flasks, and bottles. The demand for such plugs is particularly large where water samples are tested by the Most Probable Number method. It has been found that considerable experience is necessary before an individual becomes sufficiently skilled to make good plugs by hand methods at even a reasonable rate. It seemed probable to us that a simple machine could be constructed that would produce better plugs at a faster rate. Such a machine was put together from miscellaneous materials at hand in our laboratory. It consists of the following parts:

1. A one-thirtieth horse power, induction wound, electric motor.
2. A mandrel fashioned from a sixteen-penny finishing nail which was filed to a triangularly tapered point, and then polished with fine sandpaper.
3. A gear-operated speed reducer connected directly with the motor that turned the mandrel approximately 170 r.p.m.
4. A foot switch of the instantaneous action, circuit-breaker type.

The motor and speed reducer are one unit which was originally designed to revolve a brush used in washing test tubes. The chuck, in which the test tube brush was formerly placed, is used to hold the mandrel. In order to adapt this machine for use as a test tube plug wrapper, it was mounted firmly on a work bench. This was accomplished with two "C" clamps purchased at a hardware store.

Fashioning of the mandrel was relatively simple. A sixteen-penny nail was placed in a vise and the head was filed off. The ends were then reversed in the vise and the nail was filed to a triangularly tapered point which was about three-fourths as long as the plug desired. It is extremely important to polish the mandrel because file marks or other irregularities will catch cotton fibers and make the plug difficult to remove. The polishing operation should be carried out with lengthwise strokes, using very fine sandpaper. The finished mandrel mounted in the chuck on the electric motor is shown in Fig. 1.

A sensitive, instantaneous action foot switch is necessary to provide positive control of the motor. Our first switch was made from a doorbell push button mounted between two boards. This has proved satisfactory. A similar switch made for photograph enlarging machines could be adapted for use with this machine. Such a switch can be purchased at most photographic supply stores.

Received for publication, January 22, 1940.

The operation technique depends somewhat on the type of plug desired and on the operator. We have found the following system to be simple and fast:

1. A roll of cotton is separated into layers of suitable thickness. For test tube plugs an average roll is separated into three thicknesses, each of which is cut into four strips (one strip will make several plugs).

2. One end of a cotton strip is placed over the mandrel's tapered end, as is shown in Fig. 2. The machine is started by depressing the foot switch, and the cotton is fed onto the plug until sufficient material has accumulated. The plug is shaped between the thumb, index finger, and middle finger of the left hand.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 1.—View of chuck and mandrel showing manner in which mandrel is formed from a sixteen penny finishing nail.

Fig. 2.—View from the operator's position showing cotton being fed onto the mandrel. A foot switch (not shown) starts and stops the electric motor.

Fig. 3.—The finished plug is easily pulled from the mandrel when the motor is stopped.

3. At this point, with the machine still running, the strip is torn from the plug which is then finished with the fingers of the left hand. Varying pressure of the fingers will vary the tightness and hardness of the finished plugs. A finished plug is shown in Fig. 3.

4. The formed plug is now guided into a test tube, the motor is stopped, and the plugged tube is removed from the mandrel. If an extremely hard plug has been made, it may be necessary to twist the plug about one-quarter turn opposite to the direction of formation in order to detach the plug easily.

After almost one year of continuous operation the machine originally constructed is still in good operating condition. The only care it has received consisted of occasional cleaning and greasing.

A COTTON-PLUG WRAPPING MACHINE FOR BACTERIOLOGIC CULTURE TUBES AND BOTTLES

L. L. KEMPE AND H. R. SHIPMAN,* MINNEAPOLIS, MINN.

IN MANY bacteriologic laboratories large numbers of cotton plugs are required for use as stoppers in culture tubes, flasks, and bottles. The demand for such plugs is particularly large where water samples are tested by the Most Probable Number method. It has been found that considerable experience is necessary before an individual becomes sufficiently skilled to make good plugs by hand methods at even a reasonable rate. It seemed probable to us that a simple machine could be constructed that would produce better plugs at a faster rate. Such a machine was put together from miscellaneous materials at hand in our laboratory. It consists of the following parts:

1. A one-thirtieth horse power, induction wound, electric motor.
2. A mandrel fashioned from a sixteen-penny finishing nail which was filed to a triangularly tapered point, and then polished with fine sandpaper.
3. A gear-operated speed reducer connected directly with the motor that turned the mandrel approximately 170 r.p.m.
4. A foot switch of the instantaneous action, circuit-breaker type.

The motor and speed reducer are one unit which was originally designed to revolve a brush used in washing test tubes. The chuck, in which the test tube brush was formerly placed, is used to hold the mandrel. In order to adapt this machine for use as a test tube plug wrapper, it was mounted firmly on a work bench. This was accomplished with two "C" clamps purchased at a hardware store.

Fashioning of the mandrel was relatively simple. A sixteen-penny nail was placed in a vise and the head was filed off. The ends were then reversed in the vise and the nail was filed to a triangularly tapered point which was about three-fourths as long as the plug desired. It is extremely important to polish the mandrel because file marks or other irregularities will catch cotton fibers and make the plug difficult to remove. The polishing operation should be carried out with lengthwise strokes, using very fine sandpaper. The finished mandrel mounted in the chuck on the electric motor is shown in Fig. 1.

A sensitive, instantaneous action foot switch is necessary to provide positive control of the motor. Our first switch was made from a doorbell push button mounted between two boards. This has proved satisfactory. A similar switch made for photograph enlarging machines could be adapted for use with this machine. Such a switch can be purchased at most photographic supply stores.

to clinical use. That of Kodieck⁶ employs p-aminoacetophenone and few enough operations to be an apparently satisfactory routine method.

The reliability and simplicity of the method to be described as tested by its application to approximately 250 blood specimens seemed to warrant a detailed report.

DETERMINATION

Apparatus and Reagents.—Any photoelectric colorimeter, or as was used in this laboratory, a Coleman "DM" photoelectric spectrophotometer.

10 per cent sodium tungstate and 2/3 N sulfuric acid.

2 per cent potassium dihydrogen phosphate, hydrochloric acid (36 per cent) and 10 N sodium hydroxide.

4 per cent aqueous cyanogen bromide, made fresh before each group of analyses. The solid material may be purchased from Eastman and keeps well in the icebox.

Fig. 1.

Fig. 2.

Fig. 1.—Linear relation between light absorption at $\lambda = 400 \text{ m}\mu$ and amount of nicotinic acid. Colors were determined sixty minutes after start of color development.

Fig. 2.—Rate of color development in the dark using $10 \mu\text{g}$ of nicotinic acid.

Saturated p-aminophenol ("metol"). Dissolve approximately 5 Gm. in 100 c.c. of water, shake for five minutes, and filter. This must be made fresh before each series of analyses.

Method.—Five cubic centimeters of oxalated blood is hemolyzed in 35 c.c. of water, followed by 5 c.c. of 10 per cent sodium tungstate and with shaking 5 c.c. of 2/3 N sulfuric acid. After standing for ten minutes, it is centrifuged for fifteen minutes at 2,500 r.p.m. to obtain the maximum amount of filtrate. The supernatant fluid may be filtered through a moistened filter paper to eliminate any floating precipitate, and 30 c.c. of the clear filtrate is measured into a 50 c.c.

centrifuge tube bearing a mark at 10 c.c. The tube is immersed in boiling water and a strong jet of air is blown on the surface for rapid evaporation to at least the 10 c.c. mark. (In practice 4 or 6 tubes may be treated simultaneously, requiring twenty to twenty-five minutes for the operation.) Water is added to the 10 c.c. mark, and 1.6 c.c. of concentrated (36 per cent) hydrochloric acid is added and mixed. The tube is immersed in a boiling water bath for fifteen minutes, cooled, and neutralized to pH 5.0 with 10 N sodium hydroxide (approximately 2 c.c.) and with 0.5 N sodium hydroxide as pH 5.0 is approached. This can be done with sufficient accuracy by removing small samples with a glass rod and testing on Hydrion A* indicator paper. The tube is replaced in the boiling water bath and with the air stream is evaporated to the point where salt begins to crystallize out (approximately 2 c.c.). It is centrifuged briefly and the liquid is poured off into a test tube marked at 6.0 c.c. Two successive small additions of water are added, washing down the walls. After centrifugation the water is poured into the test tube to the 6.0 c.c. mark and the contents are mixed. This tube is labeled A, from which 2.0 c.c. portions are removed to tubes B and C. Tubes A and B each receive 2.5 c.c. of 2 per cent acid phosphate, and tube C receives 2.5 c.c. of 2 per cent acid phosphate containing exactly 4 μ g of nicotinic acid. The tubes are placed in a water bath maintained at 75° to 80° C. Tube A receives 0.5 c.c. of water, tubes B and C, 0.5 c.c. of 4 per cent cyanogen bromide. After mixing they are allowed to remain for five minutes, cooled, and 5.0 c.c. of saturated p-aminophenol are added to each. The tubes are inverted for mixing and are placed in a dark closet for one hour, at which time they are ready for photoelectric measurement of the yellow color produced.

If the spectrophotometer is used, the contents of tube A are poured into the "solvent" tube, then the transmission of B and C successively measured at wave length $\lambda = 400 \text{ m}\mu$. In the case of the photoelectric colorimeter, a filter transmitting maximally at this wave length should be used. Since the color of C is due both to the unknown amount of nicotinic acid + 4 μ g of nicotinic acid (reacting under identical conditions as the unknown), then the amount of nicotinic acid in the unknown can be expressed as:

$$U = \frac{\log I_0/I_B}{\log I_0/I_C - \log I_0/I_B} \times 4 \mu\text{g}$$

and in milligrams per cent of total nicotinic acid in the blood, 0.1 U.

In the case of the photoelectric colorimeters, the "zero" reading must be set with tube A, then the relations above are similar except that the log of the galvanometer readings are utilized.

The use of tube C is generally necessary in nicotinic acid analysis since salt concentration differences, pH, etc., may affect the amount of color obtained during the coupling reaction. In the case of blood analysis under these conditions it was found, however, that the same amount of color was regularly obtained from 4 μ g of nicotinic acid in the presence of the prepared blood filtrate as in pure solution. In practice, therefore, the C tube was in-

*Distributed by R. P. Cargille, 118 Liberty Street, New York, N. Y.

cluded only occasionally. With our instrument and cells 4 μg of nicotinic acid gave a log = 0.160 ± 0.004 . The useful range of the instrument employed includes values up to 1.8 mg. per cent (fasting level 0.34 to 0.45 mg. per cent). If higher values are expected, smaller samples should be used for analysis.

For nicotinic acid analysis in urine, 15 c.c. of the urine are mixed with 2.0 c.c. of 10 N sodium hydroxide and heated in a boiling water bath for thirty minutes. After cooling it is neutralized with concentrated hydrochloric acid to pH 5.0 and water is added to 20 c.c. Two cubic centimeters of this solution (one may expect from normal persons in the order of 5 μg per cubic centimeter of urine) or appropriate dilutions thereof are put into tubes A, B, and C, as described under Method.

In this case it is essential to determine for each urine or dilution, the "color yield" of a standard amount of nicotinic acid under the conditions used (difference between tubes B and C).

TABLE I

REPRODUCIBILITY OF BLOOD NICOTINIC ACID DETERMINATIONS AND RECOVERY EXPERIMENTS

SAMPLE	NICOTINIC ACID ADDED* (MG./100 C.C. BLOOD)	THEORETICAL (MG. %)	FOUND (MG. %)	RECOVERY (%)

*In normal saline.

†Corrected for the dilution of the blood caused by adding saline.

The method here described is essentially a composite of several tested methods, designed for clinical use. The data collected in Figs. 1 and 2 and in Table I demonstrate that with the procedure described (a) a perfectly straight line relation was obtained between the log of the transmission at $\lambda = 400 \text{ m}\mu$, and the amount of nicotinic acid; (b) that in the development of the color the reaction is 95 per cent complete in forty minutes, and constant from fifty-five to ninety-five minutes standing in the dark; (c) that in duplicate analyses of a single specimen of blood, results are reproducible within 6 per cent; and (d) that in recovery experiments where the nicotinic acid (in normal saline) is added directly to the blood, never less than a 92 per cent recovery was obtained in the range 3.0 to 15.0 μg of nicotinic acid.

A SIMPLE METHOD FOR THE DETERMINATION OF SERUM PROTEIN*

F. A. SIMEONE, M.D., AND S. P. SARRIS, M.D.
BOSTON, MASS.

THE Kjeldahl digestion method or one of its modifications is still the standard method for the determination of protein concentration in blood serum. The accuracy is adequate for most purposes, but the test is time-consuming. The clinical significance of the concentration of blood proteins has led to numerous investigations studying the significance of variations in blood protein level and methods of correcting hypoproteinemia (Bailey,² Allen,¹ Moon,⁸ Shuman and Jeghers.¹² The search for simple, yet accurate, methods for determining blood protein concentration has, therefore, assumed importance.

The nephelometric method of Reiss¹¹ represents an early attempt at simplification. The technique is quick and easy to learn, but its accuracy, particularly in nephrosis and lipemia, has been seriously questioned by Linder, Lundsgaard, and Van Slyke,⁷ and Guilanmin, Wahl, and Laurencin.⁶ Fishberg and Dolin⁵ suggested that the buffer action of blood is normally directly proportional to its protein concentration. They proposed a method of determining blood protein concentration, therefore, by measuring the resulting hydrogen-ion concentration of the blood after allowing it to react with a standard amount of acid. The results are reported to check very closely (within 0.5 per cent) with the Kjeldahl method. Its limitations are obvious in pathologic states in the presence of acidosis, alkalosis, or base depletion.

Moore and Van Slyke⁹ demonstrated a close, practically linear, relationship between the specific gravity of blood and its protein concentration. They showed that the specific gravity of blood represented the protein level more closely than did its refractive index and was influenced less by variations in lipid concentration. The specific gravity in their experiments was determined most conveniently by means of a specially constructed pyknometer. Barbour and Hamilton³ had previously described a method for determining the specific gravity of blood by measuring its rate of fall through an immiscible fluid under standard conditions. Their technique was of sufficient accuracy to en-

*From the Surgical Services of the Massachusetts General Hospital, Boston.
Received for publication, May 2, 1940.

able detection of hemoconcentration in dogs after emotional excitement or injection of adrenaline, and of hemodilution after sectioning the splanchnic nerves. This method, with modifications, is being used extensively in clinical laboratories to determine the specific gravity of blood or serum and to compute therefrom the concentration of protein. The calculation depends upon the empiric formula $[P = 343 (G - 1.0070)]$ of Moore and Van Slyke,² where P = concentration of serum proteins in grams per cent, and G = observed specific gravity.

Sufficient evidence has accumulated to show that the specific gravity is an accurate index of the protein concentration of blood and serum provided it can be determined with accuracy to the fourth decimal place. Both the pycnometer method of Moore and Van Slyke² and the falling-drop method of Barbour and Hamilton,³ or its modifications, have been shown to be adequate. The former, however, requires experience with the pycnometer and the analytical balance. A volume of less than 2 c.c. of fluid to be tested impairs the accuracy of the method.

The falling-drop method is accurate and can be carried out with a single drop of blood or serum, but there are many possible sources of error and experience with relatively complex apparatus is required before determinations are dependable.

A modification of the specific gravity method for the determination of serum proteins has been devised and tested. It involves the use of calibrated hollow glass beads, each of a carefully predetermined density. This report embodies a description of the method and the results of experiments with it.

METHOD

Small beads (1.5 to 2 mm. in diameter) were blown from hard glass capillary tubing and flame-polished. They were made at random in large numbers and their densities were determined individually by matching them with carefully prepared solutions of potassium sulfate (K_2SO_4) of known specific gravity at room temperature. The bead which stayed wherever placed in the standard solution without rising or falling in thirty seconds was catalogued as representing that particular specific gravity. The values were checked at least twice. Twenty-one such beads were selected as representing specific gravities of 1.0350 to 1.0172 (or serum protein concentrations of 9.60 to 3.50). Beads can thus be made to represent any desired range of protein values.

To determine the specific gravity of an unknown fluid, a bead thought to approximate the unknown specific gravity is selected and with bone-tipped forceps is placed below the surface of the unknown fluid. If the bead rises, it is replaced by one of greater density, and vice versa if it falls. If the bead shows no motion during an observation period of thirty seconds, it is taken to represent the specific gravity of the fluid tested and its protein content, in the case of blood or serum, is calculated by means of the Moore and Van Slyke formula. The test can be done in small glass test tubes of 5 mm. diameter and any convenient height. It is possible to test 0.5 c.c. of blood or even less.

RESULTS

I. The accuracy of the method in determining the specific gravity of liquids was tested by comparing its results with those obtained by the use of the pycnometer described by Moore and Van Slyke. Table I represents a comparison of specific gravities obtained by the two methods for solutions prepared by adding varying amounts of powdered glucose to aqueous solutions or to blood serum. The close agreement of the two methods is evident, the maximum difference being 0.0009; the average, 0.00047, represents for serum a protein concentration of 0.16 gram per cent. It may be concluded, then, that the bead method for determining the specific gravity of serum is sufficiently accurate for clinical purposes.

TABLE I

SPECIFIC GRAVITY OF MODIFIED* SERUM AS DETERMINED BY THE GLASS BEAD AND THE MOORE AND VAN SLYKE PYCNOMETER† METHODS (Including Figures in Table IV)

NO.	BEAD	PYCNOMETER	DIFFERENCE BEAD-PYCNOMETER
1	1.0274	1.0278	-0.0004
2	1.0278	1.0280	-0.0002

13	1.0241	1.0244	-0.0003
14	1.0269	1.0276	-0.0007
15	1.0281	1.0289	-0.0008

Average difference in specific gravity = $0.00047 = 0.16$ per cent protein. (Specific gravity 0.0001 = 0.0343 per cent protein.)

*Serum modified by adding solid glucose or distilled water.

†The pycnometer used here had a capacity of 10 c.c.

II. The serum protein concentration was determined in eighty-eight specimens of blood by the micro-Kjeldahl method and by the bead method described above. Fifteen more specimens were determined in duplicate. The thirty specimens were submitted for determination by both methods as unknowns.

Table II compares the results obtained by the micro-Kjeldahl and the bead specific gravity method in twenty representative determinations. The close agreement of the two methods is striking. The maximum difference between the results obtained by the bead and micro-Kjeldahl methods is 0.8 Gm. per cent. This difference appeared in only two of the 118 determinations. In two others the difference was 0.7 Gm. per cent, in one it was 0.6 Gm. per cent, and in nine it was 0.5 Gm. per cent. The average difference was 0.25 Gm. per cent.

Table III shows the results obtained in ten representative specimens out of fifteen which were determined as unknown duplicates by the two methods. It will be seen that closer checks, as a rule, are obtained by the bead method than by the micro-Kjeldahl digestion method.

III. The effect of glucose concentration on the specific gravity of blood serum. The glucose concentration of normal blood serum was varied by the addition of powdered glucose and the specific gravity of the solution was determined by the bead method in seven instances. In five of these, it was determined also by the pyknometer method. The results are shown in Table IV and graphically in Fig. 1, in which the specific gravity difference is converted to the serum protein

concentration difference in grams per cent. Reference to these data demonstrates a practically linear error in the estimated serum protein concentration introduced by variations in the glucose concentration of the blood serum. This observation is of significance clinically for blood protein determinations done in patients with diabetes mellitus.

Fig. 1.—Graph relating glucose concentration of serum to specific gravity. Ordinates: specific gravity recorded as protein concentration; abscissae: glucose concentration; crosses: values obtained by pycnometer method; dots: values obtained by glass bead method.

DISCUSSION

The foregoing data demonstrate the practicability of a method for the determination of serum proteins, depending upon the virtually linear relationship between specific gravity and protein concentration. The specific gravity is accurately measured by means of hollow glass beads of previously determined density. Bing⁴ described a specific gravity method for determining serum protein by the use of a single bead representing a specific gravity of 1.0158 (protein concentration of 3.0 Gm. per 100 c.c.). Three cubic centimeters of serum are used and diluted with 0.9 per cent sodium chloride until the bead neither rises nor falls. At room temperature (20° C.) the diluted volume represents the protein concentration of the serum. The accuracy of the method depends in part upon the accurate delivery of 3.0 c.c. of serum. An error of 0.1 c.c. will introduce an error of 3.4 per cent in the total protein concentration. If smaller volumes of serum are used, the error will be correspondingly greater. It is convenient that it involves the use of only one bead. This advantage over the method described here loses significance when it is considered that once a set of beads is prepared, it can be used indefinitely and the necessity of volumetric instruments and diluting fluid is obviated.

The accuracy of any method depending upon the relationship between specific gravity and serum protein concentration could be influenced by a number of factors. The effect of changes in the albumin-globulin ratio was studied

by Nugent and Towle.¹⁰ They observed no significant effect of varying the albumin-globulin ratio of beef serum. Increases in the lipid concentrations likewise have relatively little influence on the specific gravity of serum (Moore and Van Slyke). The slight shifts that take place in the concentration of blood solids when the protein level changes have been found to be of no practical significance (Weech, Reeves, and Goettseh¹³). The data in Table IV show that abnormal concentrations of blood glucose may introduce a significant error in the protein concentration computed from the specific gravity. Sufficiently accurate corrections may be made by deducting 0.1 Gm. per cent protein for each increment of 100 mg. per cent glucose.

Certain precautions should be observed in determining specific gravity by the method described here. The beads are best kept in a padded partitioned box and handled with bone-tipped forceps. The blood or serum is placed in small glass tubes held vertically in a plasticine base. Determinations are done at room temperature. To avoid surface tension effects, the bead is placed in the solution directly below the surface. An air bubble may be carried down with the bead and should be carefully shaken off when present. Currents are sometimes set up in the fluid by the mere introduction of the forceps into it, particularly when tubes of larger diameter are used. If the bead is observed for thirty seconds, however, the effect of currents will have been spent. The beads, of course, should be kept clean, and this is easily accomplished by rinsing them in distilled water immediately after removing them from the blood or serum.

The method for blood protein determination presented in this report is offered as a quick, simple, yet accurate, one. No contention is held that this method is more accurate than the other specific gravity methods or the Kjeldahl method, but, since the technique is simple and sources of error are minimized, it will find greater adaptability in clinical research. For ordinary clinical purposes it is hardly necessary to have more than four calibrated beads representing serum protein concentrations of 5.0, 6.0, 7.0, and 8.0, respectively. With experience, it becomes simple to interpolate between beads and read values to within 0.25 Gm. per cent. Greater accuracy in the clinic is seldom required.

SUMMARY

1. A method for the estimation of blood or serum protein concentration is described, depending upon the determination of the specific gravity of the fluid by means of calibrated hollow glass beads.
2. The method compares favorably in accuracy with other reported techniques. Its advantages are its sensitivity, its simplicity, and its requirement of very small volumes.
3. The effect of glucose concentration on the determinations has been tested and a graph is presented (Fig. 1) from which corrections may be made.

NOTE ON A POSSIBLE SOURCE OF ERROR IN THE DETERMINATION OF SULFAPYRIDINE AND SULFANILAMIDE*

MARY FRANCES BUTLER, M.S., AND SAMUEL B. NADLER, Ph.D., M.D.
NEW ORLEANS, LA.

THE twofold purpose of this paper is (1) to point out a possible source of error in the determination of sulfanilamide and sulfapyridine, and (2) to indicate that concentrations of procaine hydrochloride as low as 0.01 mg. per cubic centimeter of blood may be determined with a high degree of accuracy, thus making available a method for the study of the metabolism of procaine hydrochloride.

In the course of a series of sulfapyridine determinations on a patient to whom sulfapyridine was administered parenterally at a constant rate, it was observed that there was a rather marked fluctuation in the blood level of sulfapyridine. The fluctuation in blood level did not correspond to alterations in the dose or rate of administration of sulfapyridine. It was apparent, therefore, that some contaminant might possibly be responsible for the observed fluctuations. Upon inquiry it was found that it has been common practice for hospital interns to collect venous blood in syringes which had been used to anesthetize the skin, with 2 per cent novocaine (procaine hydrochloride), prior to venipuncture.

It should be noted that the color development of sulfapyridine and sulfanilamide depends upon diazotization of primary aryl amines. Procaine hydrochloride is a primary aryl amine and diazotization of its amine group, when the sulfapyridine reagents are added, according to the method of Marshall,¹ results in a pink color which is identical in tinctorial power with that obtained

*From the Joseph Hume Research Laboratory, Touros Infirmary, and the Department of Medicine, Tulane University School of Medicine, New Orleans.
Received for publication, May 10, 1940.

from sulfapyridine. As an indication of the magnitude of this source of error, it was found that after one drop of 2 per cent procaine hydrochloride is added to 5 c.c. of blood, a sulfapyridine value of 12.3 mg. per cent was found. There is no significant diminution in the value if the blood is allowed to stand at room temperature for two days.

An attempt was made to recover added procaine hydrochloride from blood to determine the lower limits of sensitivity of the method. Accordingly, procaine hydrochloride was added to blood in amounts sufficient to yield final concentrations of 1.0 and 2.0 mg. per cent. Precipitation of the blood was then carried out in 1:10 and 1:20 dilutions. The recovery of procaine hydrochloride from the blood containing 1.0 mg. per 100 c.c. was 1.02 mg. per cent in the 1:10 dilution of the blood, and 1.04 mg. per 100 c.c. in the 1:20 dilution of the blood, an error of plus 2 and plus 4 per cent. Recovery of procaine hydrochloride from blood containing 2.0 mg. per cent with 1:20 dilution was 2.14 mg. per cent, an error of plus 7 per cent. In these determinations the blood estimation was matched with a known procaine hydrochloride standard.

TABLE I

STANDARD SODIUM SULFAPYRIDINE MOL. WT. 271 (MG. %)	STANDARD SULFANILAMIDE MOL. WT. 172 (MG. %)	STANDARD PROCAINE HCl MOL. WT. 272 (MG. %)	DETERMINED PROCAINE HCl (MG. %)	CALCULATED PROCAINE HCl CONCENTRATION (MG. %)
-	0.20	0.20	0.130	$0.13 \times \frac{272}{172} = 0.20$
-	0.40	0.40	0.256	$0.256 \times \frac{272}{172} = 0.40$
0.20	-	0.20	0.200	$0.200 \times \frac{272}{271} = 0.20$
0.40	-	0.40	0.396	$0.396 \times \frac{272}{271} = 0.39$

It now seemed desirable to determine the tinctorial power of procaine hydrochloride as compared to sodium sulfapyridine and sulfanilamide. Standard 0.2 per cent and 0.4 per cent solutions of these substances were prepared. As may be seen in Table I, the color developed by procaine hydrochloride is practically identical with that developed by sulfapyridine—the molecular weights are nearly identical. When procaine hydrochloride is matched with standard sulfanilamide, procaine hydrochloride only develops about 64 per cent as much color. However, the ratio of the molecular weights of procaine hydrochloride and sulfanilamide is $\frac{172}{272} = 1.58$, indicating a 100 per cent recovery on an equimolecular basis. It is apparent then that on an equimolecular basis the tinctorial power of procaine hydrochloride is equal to that of sulfanilamide and sulfapyridine.

OBSERVATIONS WITH A PHOTOELECTRIC HEMOGLOBINOMETER*

PAUL L. McLAIN, M.D., AND GEORGE J. PASTORIUS, M.D.
PITTSBURGH, PA.

PHOTOELECTRIC colorimeters have been adapted to many measurements including the quantitative estimation of hemoglobin. Reported observations indicate the feasibility of rapid and fairly precise hemoglobin measurement by the use of such instruments.¹⁻⁶ The present study was undertaken to survey the characteristics of a photometer designed particularly for use as a hemoglobinometer.

THE INSTRUMENT

The instrument used was a simple form of photoelectric colorimeter,[†] consisting essentially of a single photoelectric cell, a filter, a holder for solution containers, and a light source. The photoelectric cell was of the blocking layer type, the output being measured with a sensitive galvanometer built into the instrument. The lamp was energized by a pair of dry cells incorporated in the instrument case. The solution containers were commercially obtainable test tubes selected for uniformity in size of bore. The holder for the solution containers was of special construction to compensate for optical defects inherent in a cylindrical form of solution cell. Fig. 1 shows the general appearance of the instrument.

The apparatus was operated as follows: With the lamp off, the galvanometer needle was adjusted to a prescribed zero point at the right extremity of the scale by manipulating a small knob mounted on top of the instrument (Fig. 1). The lamp was then lighted, and a solution cell containing freshly distilled water was placed in the holder. This procedure caused movement of the galvanometer needle to the left. The needle was then adjusted to the left extremity of the scale by altering the lamp intensity by means of a rheostat provided on the front of the instrument (Fig. 1). The tube containing distilled water was then replaced by one containing an unknown solution of acid hematin prepared as noted below. The decreased transmission of light caused a deflection of the galvanometer needle to the right for a distance dependent upon the concentration of acid hematin present in the solution. For most consistent results the instrument was allowed to stand with the lamp lighted for about five minutes prior to the first reading. Before use tubes for solutions were carefully cleansed inside and out.

Received for publication, May 24, 1940.

†This photometer was an experimental model supplied by the Fisher Scientific Company, Pittsburgh, Pa.

EXPERIMENTAL PROCEDURE AND RESULTS

Five samples of beef blood, one of sheep blood, and two of human blood were examined. Upon each of these the following observations were made:

- a. Oxygen capacity by the manometric method of Van Slyke and Neill,⁷ carried out in duplicate or triplicate.
- b. Oxygen capacity by the blood iron method of Wong.⁸
- c. Photometer readings, after appropriate treatment, of whole blood and of dilutions with 0.9 per cent sodium chloride solution containing 80, 60, 40, and 20 per cent whole blood.

Fig. 1.—General view of photoelectric hemoglobinometer.

Samples of whole or diluted blood were prepared for photometric studies by diluting in a special pipette 20 c.mm. of the sample with 5 c.e. of tenth-normal hydrochloric acid. The resulting acid hematin solution was discharged into a solution cell and allowed to stand for five minutes. Although the color was not fully developed in this length of time, results were sufficiently consistent for practical purposes. Three or more photometer readings were made for each test, the galvanometer zero being reset, if necessary, between readings.

Table 1 shows the relationship of hemoglobin content, calculated from oxygen capacity, to photometer readings expressed in arbitrary units of the galvanometer scale. This relationship is shown graphically in Fig. 2, which is based on hemoglobin values obtained by the gasometric method. In the preparation of Fig. 2 hemoglobin contents of blood dilutions were calculated from the values determined for respective samples of whole blood.

TABLE I

RELATIONSHIP OF THE HEMOGLOBIN CONTENT OF BLOOD TO PHOTOMETER READINGS

BLOOD NO.	NATURE OF BLOOD	O ₂ CAPACITY		HEMOGLOBIN		PHOTOMETER READING UNITS
		GASOMETRIC (VOL. %)	BLOOD IRON (VOL. %)	GASOMETRIC (GM. %)	BLOOD IRON (GM. %)	
2	Sheep	15.45	16.40	11.6	12.3	36.0
3	Beef	16.49	16.87	12.4	12.7	35.3
4	Beef	21.31	22.10	16.0	16.6	40.2
5	Human	11.48	13.20*	8.6	9.9*	30.0
6	Human	8.97	10.12*	6.7	7.6*	25.8
7	Beef	19.99	20.50	15.0	15.4	38.6
8	Beef	22.66	23.25	17.0	17.5	42.2
9	Beef	22.29	22.47	16.7	16.9	41.3

*Patients supplying these samples were receiving iron medication daily.

Fig. 2.—Relationship of photometer readings to hemoglobin concentration, based on gasometric hemoglobin determination.

DISCUSSION

The characteristics of this particular type of photometer favored its application to hemoglobin estimations. Operation was simple, requiring less than ten minutes for a complete determination. The amount of blood required was small and the final dilution was high, conditions which tend to minimize the effects of technical errors in sampling and dilution. As shown in Fig. 2, the calibration curve was quite flat, especially in the clinically important low hemoglobin range. Single readings were reliable within one unit on the galvanometer scale in approximately 90 per cent of consecutive trials. A deviation of one scale unit was equivalent to 0.3 Gm. of hemoglobin per 100 c.c. of blood below 5 Gm. total, 0.3 to 0.5 Gm. between 5 and 10 Gm. total, and 0.5 to 0.7 Gm. between 10 and 15 Gm. total hemoglobin content. Repetition of photometer readings was but a matter of seconds and naturally reduced the error of single readings.

A point of incidental interest was the comparison of hemoglobin measurements by gasometric and blood iron methods, as shown in Table I. The iron

method gave results consistently higher than those obtained by gasometric determination, the average difference amounting to 0.61 Gm. of hemoglobin per 100 c.c. of blood. The widest discrepancies occurred in the two human samples, both from anemic patients receiving large daily doses of iron. If these two samples are neglected, the average difference between results by the two methods was 0.45 Gm. per 100 c.c. We are inclined to agree with Haden⁹ that either method is suitable for normal bloods, and that the relative simplicity of the iron method is a definite advantage. However, it seems clear that the true respiratory value of the blood is more accurately portrayed by the gasometric measurement.

SUMMARY

1. The characteristics of a simplified form of photoelectric hemoglobinometer were studied by comparison of photometer readings with hemoglobin measurements according to the gasometric method of Van Slyke and Neill and the blood iron method of Wong.
2. The photometer employed was found to be suitable for hemoglobin measurements.
3. Single readings were reliable within 0.3 to 0.7 Gm. of hemoglobin per 100 c.c., depending on the total hemoglobin content of the sample. Multiple readings, occupying an insignificant amount of extra time, narrowed the limits of error.
4. Comparison of hemoglobin estimations by gasometric and blood iron methods was included in the study.

It is a pleasure to acknowledge the helpful suggestions of Dr. C. C. Guthrie.

A TECHNIQUE FOR THE DETERMINATION OF PROTHROMBIN TIME*

DANIEL A. SHERBER, M.D., BROOKLYN, N. Y.

WITH the introduction of the effective use of vitamin K in the treatment of hemorrhage in jaundice by Warner, Brinkhous, Smith¹; Butt, Snell, Osterberg²; Dam and Glavind,³ the need for a practical and accurate method of determining the prothrombin content of the blood, now known to be related to vitamin K absorption, has assumed increasing importance.

The techniques for prothrombin determination have been limited to two accepted methods: that of Dam and Glavind⁴; which is extremely time-consuming and laborious; and that of Quick, which is more practical for clinical purposes, and the more widely used of the two. Even the method of Quick,⁵ however, is burdensome, since it does not include a stable thromboplastin, and therefore requires frequent renewal of the preparation.

During the past year a technique has been developed and successfully employed in our laboratories which eliminates the above-mentioned disadvantages of time and complexity, and so facilitates the increased use of prothrombin determination, that we feel it merits a detailed description.

The apparatus employed consists of a constant temperature water bath, set at 40° C., and an anatomic museum jar, measuring 25 by 21 by 9 cm., with sides of fairly uniform thickness, as the water tank. The heat source is a knife-blade heater connected to a mercury thermoregulator by means of a magnetic relay. The water between the heater and thermoregulator is kept in motion by a stirrer attached to the shaft of a slow motor, as illustrated in Fig. 1.

The reagents required are a potent thromboplastin extract and a 1/40 M calcium chloride solution. The thromboplastin is obtained by extraction from the brains of stillborn fetuses. To obtain consistent results with extracts prepared by this method, from a number of brains, the brain should not be kept in the refrigerator for more than thirty-six hours after death. To prepare the brain for extraction, the pial membranes and vessels are removed as completely as possible, and the brain is cleaned by immersing for a moment in cold water. It is then weighed, cut into small pieces, and put into a large mortar. An equal weight of pure sand is added and the mixture is ground with a pestle until it has an even creamlike consistency. To this mixture is added an approximately equal volume of normal saline and thoroughly mixed. The material is then centrifuged until the supernatant fluid is only slightly cloudy. This takes approximately one to one and a half hours. The fluid is then poured off, filtered through cotton, sealed in 5 c.c. vials, and kept frozen by storage in a freezing chamber. Thromboplastin prepared from a single brain and stored in

*From the Department of Laboratories, Jewish Hospital of Brooklyn, Dr. Max Lederer, Director.

Received for publication, June 24, 1940.

this manner has been kept for six months without any signs of deterioration in potency, and has been sufficient in quantity for approximately 200 determinations.

Fig. 1.—*a*, Knife blade heater; *b*, mercury thermoregulator; *c*, light source.

In preparation for the test a vial of the thromboplastin extract is defrosted in warm water, and an equal volume of $1/40$ M calcium chloride solution is added to it. This mixture is then immersed in the water bath, which is kept at

40° C., and allowed to incubate for thirty to forty-five minutes, after which time it will be noted that a flaky white material has been precipitated, and the supernatant fluid is almost clear. This fluid is centrifuged at high speed (about 2,000 r.p.m.) for ten minutes until clear, and the clear fluid is then returned to the water bath.

Fig. 2.—a, Ground glass surface for labeling.

Fig. 3.

To collect the blood sample, 15 c.c. calibrated centrifuge tubes, containing 0.5 c.c. of 3 per cent sodium citrate solution, are used, to which 5.5 c.c. of blood are added, giving a total of 6 c.c. The plasma and cells are separated by centrifuging at 2,000 r.p.m. for five minutes, as soon as received, the plasma being kept in the refrigerator until used for the determination. Blood collected and treated in this fashion will yield a plasma which will give reliable results even after twenty-four hours, in contrast to the thirty minutes previously considered safe.

To determine the prothrombin time, 0.1 c.c. of plasma is pipetted into special round bottom tubes (Fig. 2), which in the meantime have been allowed to come to the temperature of the water bath. The plasma is incubated in the water bath for five minutes. Approximately 0.2 c.c. of the calcium chloride thromboplastin mixture is drawn up into the aspirator (Fig. 3) and is quickly expelled into the tube containing the plasma. At the same time the stop watch is started. The tube is viewed at right angles to the source of illumination, and when clotting appears, manifested by the beginning of opacity, the watch is stopped. (The reading of opacity is greatly facilitated by painting the back of the water bath black.) The time noted is the prothrombin time. By this method normal human plasma has a range of 10 to 13.3 seconds and an average of 12.1, with a mean variation of 0.7 second. With but little experience one can repeat readings on a given sample of plasma within 0.6 second. For routine work three readings are done; these should agree with each other within the limits of one second.

Recently I have used a thromboplastin extract prepared from brains as those described, but have varied the method somewhat to eliminate the necessity for adding calcium chloride at the time of determination. In this case, the extraction medium is a solution of 1/40 M calcium chloride in normal saline. A mixture of these two substances is centrifuged and stored in vials as described above. If, when doing the determination with this extract, one desires a greater volume of thromboplastin extract, addition of an equal volume of normal saline will not diminish its potency. With this preparation it is important that the extract incubate in the water bath for forty-five minutes before centrifuging. Results with this extract on normal plasma are somewhat higher than those described. By this method normal human plasma has a range of 15.3 to 24.9 seconds and an average of 20.8, with a mean deviation of 1.9 seconds. This extract has proved as stable and reliable as the one originally used.

Experiments with a thromboplastin extract in which an equal volume of 1/40 M calcium chloride solution was added to the thromboplastin after its extraction with normal saline and then stored as mentioned above, yielded an extract similar in potency to the one extracted with 1/40 M calcium chloride in normal saline. This preparation, however, showed evidence of deterioration after two months. The use of stillborn fetus brains has yielded a thromboplastin superior in activity and stability to that extracted from the brains of embryo and adult cattle and rabbits, as well as adult human beings.

SUMMARY

1. The preparation of a stable and potent thromboplastin extract which eliminates the repeated extraction of thromboplastic material is described.
2. A description of a simple, inexpensive, and reliable technique and apparatus for the determination of prothrombin time is presented.

Sincere thanks are extended to Mr. Bernard Sobel, of the Division of Chemistry, for his aid in assembling the apparatus.

THE IMPORTANCE OF TEMPERATURE FOR COLORIMETRIC DETERMINATIONS*

WITH SPECIAL REFERENCE TO NESSLER'S REACTION

LUDWIG PINCUSSEN, M.D., PH.D., CHICAGO, ILL.

COLOR reactions for determining biological constituents are widely used in this country. In most cases the colored solutions to be compared display a more or less colloidal behavior.

A few incidental observations showed that for one of these colorimetric methods, the yellow color produced by adding Nessler's reagent to ammonium sulfate solutions obtained by digesting urine with sulfuric acid, is very dependent upon the temperature.

As shown by many investigators the color produced by Nessler's reagent in solutions of ammonia goes parallel to the amount of nitrogen whether the ammonia was obtained by distillation or the nitrogen solution digested by sulfuric acid was immediately used for the test (direct nesslerization).

To avoid complications resulting from the digesting of organic material in the way commonly used for nitrogen determinations, the following experiments were made with pure ammonium sulfate solutions.

Into each of two large test tubes graduated to 35 and 50 c.c., 5 c.c. of ammonium sulfate solution containing 1 mg. of nitrogen were pipetted, 1 c.c. of sulfuric acid solution (1 c.c. of concentrated sulfuric acid, 1 c.c. of water) added and made up to 35 c.c. with water. The tubes were kept in ice water for fifteen minutes. Nessler's reagent just taken from the refrigerator was slowly added to the mark 50, mixed, and the tubes left in the ice water for three more minutes. After this time one tube was left in the ice water, the other was taken out and kept at room temperature.

Both cups of the colorimeter were filled with the solution in ice water. Readings were in the beginning 30:30; after being left in the cups ten minutes, 30:29.7; after twenty minutes, 30:29.6; after thirty minutes, 30:29.7. Thus the readings were practically constant for the solutions, ice cold in the beginning being warmed together to room temperature by standing in the cups.

The solution (now at room temperature) was left in one of the cups and the solution in the other cup replaced by new solution kept at room temperature but the reading did not change, 30:29.5, 30:29.8. Thus with both solutions at the same temperature the reading is correct and stays that way.

When the room-warm solution was left in one cup and cold solution (from the test tube in ice water) was substituted in the other cup, the reading was

*From the Department of Physiological Chemistry, University of Illinois, College of Medicine, Chicago.

Received for publication, July 1, 1940.

30:17.5 (30 being the layer of the ice-cold solution). While the solutions were in the cup, the temperature of the cold solution slowly went up, the reading went down to 30:24, and after thirty minutes to 30:29, practically reaching the correct reading.

If the cups were emptied and one cup was filled with ice-cold solution and the other with solution at room temperature, the reading was 30:17.5 and went down to 30:25, and finally to 30:30, when the solutions had reached the same temperature. These experiments were duplicated in manifold ways. Parts of the same nesslerized solution showed the phenomenon, if one-half was kept cool, the other half at room temperature, and the difference in reading could almost be reversed by reversing the temperature of the solutions. The changes of the optical transmission of these solutions were hardly visible to the naked eye; the solutions looked clear and transparent. It may be added that there was no difference whether a protective colloid was added or not.

The explanation of these findings is, of course, given by the colloidal status of the solutions, the optical transmission being decreased by raising, and increased by lowering the temperature. As far as can be seen in these few experiments this process is, at least for a certain time, more or less reversible. Theoretical questions cannot be discussed in this paper.

Some other color reactions, such as the determination of phosphorus with hydroquinone-molybdic acid (Bell and Doisy) and the determination of glucose with the Benedict method did not show this influence of temperature.

Using Nessler's method, whether with or without preceding distillation and with or without protecting colloid, care must be taken that the temperature of the solutions in the cups is the same. For practical purposes the best procedure seems to be to add cold Nessler's reagent to the cold solutions to be compared, add if desired the protective colloid, mix, leave the solutions in the cold for ten minutes, take them out and let them stand for twenty minutes at room temperature. In this way the solutions have the same temperature and are aged to the same degree. For each reading not only the solution to be tested but also the standard solution may be put in the cups at the same time, thus avoiding the danger of unequal warming by the light source.

MEDICAL ILLUSTRATION

CLINICAL LABORATORY PHOTOGRAPHY WITH A NEW METHOD OF PREPARING PHOTOMICROGRAPHS*

WRAY J. TOMLINSON, M.D., MONTGOMERY, W. VA.

THE value of a simple and inexpensive method of routine photography for use in the modern clinical laboratory need not be emphasized. Indeed, there are few institutions possessing aggressive staffs which have not recognized the value of such facilities and attempted a solution. Few hospitals that are not directly associated with teaching institutions or research laboratories have the services of trained photographers for their requirements. The responsibility is usually relegated to the pathologist or radiologist who far too frequently has not had the opportunity for study or experience in this field. As a result, the prospect of starting such a department is alarming from the triple viewpoint of expense, time involved, and results produced.

For those laboratories and institutions already possessing cameras and equipment suitable for gross and photomicrographic work, the methods outlined here may be of little value. There is no denying the fact that better photographs are easier to obtain by using more expensive precision apparatus and larger film sizes or plates; however, it is possible to work with 35 mm. film and obtain excellent results. It might be found advantageous in terms of simplicity and economy to consider the procedure given here for routine photomicrographic work. Hellwig¹ has stressed the need for such procedures and given a method. To the best of my knowledge there has been no prior publication dealing with photomicrographs by the method here described, yet from its very simplicity it must have been used.

GROSS AND CLINICAL PHOTOGRAPHY

Equipment.—The equipment listed here is for the convenience of those desiring such information. There are many other similar cameras and apparatus available which undoubtedly will do equally as satisfactory work. The following equipment can be purchased for less than one hundred dollars.

1. Argus C₂ 35 mm. camera, or for those desiring photoflash equipment the C₃ is available at a slight additional cost.
2. The Arguscope, which essentially gives accurate ground-glass focusing for close work.
3. Photoelectric cell type light meter.

*From the Laird Memorial Hospital, Department of Pathology, Montgomery.
Received for publication October 10, 1940.

4. Any 35 mm. film enlarger. A considerable saving can be effected by using an enlarger that will accommodate the camera lens.

Technique.—For photographing patients, equipment, and large specimens, or for use in the necropsy room, the camera alone is satisfactory. It is equipped with a coupled range finder, and accurate focusing from three feet can be done easily.

The Arguscope is invaluable in photographing surgical, necropsy, or other small objects. Full instructions are supplied by the manufacturers and are extremely simple. Photographs may be taken covering fields from $8\frac{1}{2}$ by $12\frac{3}{4}$ inches down to 1 by $1\frac{1}{2}$ inches, and at distances from $19\frac{1}{2}$ inches down to $3\frac{3}{4}$ inches from the object. The use of the ground-glass attachment for critical focusing and composition enables the routine production of prints of excellent quality.

Mallory² gives directions for preparing a tank devised by Bitterman for photographing specimens. The use of a tank is satisfactory, although in using 35 mm. film a smaller tank, that is, one that encompasses a field equal to the area covered by the camera, is also satisfactory. The purpose of photographing specimens under water is to eliminate annoying high lights. A defect that develops from lighting the specimen while under water is flatness or a lack of modeling. It is advisable, therefore, that one of the lights be placed at an acute angle to produce modeling. A far better method of eliminating high lights and still preserving the modeling is to light the specimen through a tracing cloth screen as described by Schmidt and Haulenbeck.³

The background of gross specimens may be made white on the print by using an auxiliary light beneath a glass base upon which the specimen may rest. The same thing can be accomplished by opaquing the background in the negative. However, the former method is easier and better. A more complete discussion of this subject will be found in another publication.⁴

The use of a celluloid ruler provides an easy method for critical focusing and in addition gives an easily interpreted scale for determining the size of the specimen from the prepared photographs. The ruler should be placed one-third distance from the top of the specimen, or two-thirds distance from the background. After focusing on the ruler, the diaphragm is closed as far as possible to obtain the maximum depth of focus. When the specimen is placed on a clear glass background with a light beneath, a transparent celluloid ruler is most effective.

Film, including the 35 mm. size, is available in many different types of emulsions. I have found the Eastman Panatomic X, processed in the Eastman DK-20 developer, to be the most satisfactory for general use in clinical and gross specimen photography. This 35 mm. film may be purchased in handy cartridges already prepared by the manufacturer, although a considerable saving may be effected by the use of bulk film. The almost routine photographing of surgical specimens and the attaching of prints to the completed reports necessitate development of the negatives fairly soon after their exposure. By purchasing film in bulk quantities and loading old cartridges with film lengths between twelve and fifteen inches, one is able to obtain eight to ten exposures for

each strip, instead of waiting several days as is often necessary to complete the exposures on a long roll of film. The DK-20 developer can be used for a considerable number of such strips without appreciable deterioration.

Fig. 1.—A, Cone-shaped adapter for fitting on microscope to hold the lantern slide. B, Cardboard enlarger carrier to hold 2 by 2 inch negative. C, Enlarger to hold 1 by 3 inch microscope slide.

Miniature camera work is extremely well adapted to the use of color film, and Kodachrome transparencies (type A, indoor) add greatly to the value of the work performed. For viewing these transparencies a regular 2 by 2 inch projector is available, or the larger-sized projectors may be converted by a simple attachment to handle the 2 by 2 inch sizes. In the event these adapters are used on the large projectors, it is advisable also to change the lens of the large projector to one of a shorter, proper focal length. In this manner the image on the screen will be the same size as the image projected from the larger slide, provided the projector is at the same distance from the screen. In changing back to the larger slide it becomes necessary to change the lenses again.

An attractive method of displaying these 2 by 2 inch transparencies, and likewise keeping them, has been developed by the Filmdex Corporation of McKeesport, New York.

Extremely satisfactory colored photomicrographs for projection or use as transparencies for museum purposes can be prepared very simply from black-and-white lantern slides by the method described by Putnam.⁵ This method is also applicable to the preparation of transparencies by means of Eastman Translite enlarging paper.

PHOTOMICROGRAPHS

The Arguscope can be used in photomicrographic work if desired. The results are variable; however, the method given here has proved satisfactory.

The equipment required is minimal, provided one possesses a microscope and a lamp. Beyond these, a darkroom, the adapter to be described, and a supply of 2 by 2 inch medium lantern slides are all that are necessary. The adapter consists of a cone (Fig. 1A) which fits over the monocular tube and accommodates the ocular. The tube shown in the illustration measures $5\frac{1}{2}$ inches in total length and $1\frac{7}{8}$ inches in diameter at the top. However, these tubes can be made in different lengths according to the additional magnification or reduction that is desired in relation to the objective and ocular used. By doubling the length of the tube the magnification is increased about one-fourth. Of course, if a bellows is used in place of the tube, the image can be varied to fill out the film with a specific composition. The exact magnification can then be determined by means of a stage micrometer. The inside of the adapter or bellows is painted dull black to prevent light reflections. These adapters are easily prepared or can be obtained from H. F. Holmes, Montgomery, W. Va., for two dollars. A bellows and the necessary supports would be more expensive.

In use the adapter is fitted to the microscope, as shown in Fig. 2, and the top of the cone is covered by a piece of ground glass, measuring 2 by 2 inches, with the ground surface down. This is easily prepared by removing the emulsion from a 2 by 2 inch lantern slide and then rubbing briskly with a valve grinding compound, procurable at any garage, until an evenly ground surface is obtained. The placing of penciled cross lines in the center enables one to focus accurately on the ground surface.

The lamp is tilted or twisted until the beam of light from the condensing lens falls squarely on the center of the microscope mirror. The condensing lens in the best lamps for photomicrography is adjustable, so that the beam can form a small spot on the mirror. The smaller this spot the more intense is the light, thus making short exposures at high magnifications possible. Lamps that are more suitable for photomicrography are the ribbon filament, the arc, the Point-o-lite, and the new photomicrographic lamp of Bausch & Lomb Optical Co and General Electric Co. The arc is the most common in use, but the ribbon filament lamp is rapidly taking its place. The Point-o-lite is an excellent light source but somewhat difficult to use. The new photomicrographic light is not yet in common use and its value, therefore, cannot be judged. In any event, the beam of light is centered accurately, the condenser of the microscope is brought into focus, and the objective filled with light; these procedures are necessary in all photomicrographic work and are accomplished easily. A slide is inserted and the microscope is brought into focus on the ground glass; the focus is checked by means of a hand lens. The field desired to be reproduced

is selected; obviously, it should be free from defects or artifacts. The microscope lamp is turned off, the ground glass is removed, and a 2 by 2 inch film or plate is put in place.

Fig. 2.—Microscope showing the adapter in place. In this picture the ribbon filament 6 volt lamp is used. This lamp has a condensing lens for spotting the light on the mirror of the microscope and a holder for two filters which are seen in place. Other light sources are discussed in the text. The lenses used in making the pictures seen in Fig. 3 are also shown. The box is for holding the various color filters.

In considering the sensitized negative materials most suitable for photomicrography, one should choose the type of film or plate on the basis of contrast desired and its sensitivity to the colors to be recorded. Most workers find it desirable to use a plate of high available contrast, high resolving power, and general sensitivity to all colors. The Wratten M plate for all types of photomicrography that do not require extreme sensitiveness is generally used. This plate, if properly employed, will produce negatives of a wide range of contrast, depending on the factors of varying the exposure and developing time. Photographic plates having only the original color sensitivity of the silver salts to ultraviolet, violet, and blue lights are technically considered to be "ordinary" plates (commercial and process), and may be developed in red light. When the sensitivity is extended by dyes into the green, the plates are orthochromatic. These, too, may be developed in a red light of low intensity. Panchromatic materials are sensitive throughout the whole visible spectrum and sometimes even beyond, into the near infrared.

With panchromatic material it is generally necessary to use a light filter between the light source and the condensing system of the microscope. It is best to select the desirable filter by visually inspecting the subject through filters until one is found that shows up the subject to best advantage. No one filter will fit all cases, nor can the filter be disregarded in every instance in

FIG. 3.—Photomicrographs showing s kidney tissue. A $\times 7$ ocular was used on objectives were as follows: A, Micro Tess Apochromat; D, $\times 20$ Apochromat; E, $\times 40$ lower photomicrograph of a parasite.

of the same area of magnifications of the Apochromat; C, $\times 10$ omat; G, A typical low

spite of the fact that a process or process panchromatic plate will at times give the desired contrast and detail in the resulting negative.

The book *Photomicrography*⁶ gives the following table which is of assistance in choosing a filter suitable for specific cases:

Use for blue stained preparations	a red filter
Use for green stained preparations	a red filter
Use for red stained preparations	a green filter
Use for yellow stained preparations	a blue filter
Use for brown stained preparations	a blue filter
Use for purple stained preparations	a green filter
Use for violet stained preparations	a yellow filter

In some cases it is necessary to use two filters and panchromatic material to obtain the best results. For example, a green and a yellow filter in combination often show up the hematoxylin-eosin stained section most satisfactorily.

All the foregoing photographic work can be done in a darkroom, provided the plate or film is not incased in a holder or magazine. Exposure of the film can be made by snapping the microscope light on and off; only a few trials are needed before one can accurately judge the correct exposure. Development is carried out in total darkness with the time and temperature method if panchromatic material is used; otherwise the ruby light is employed and some control over density is possible. It is also permissible to use lantern slide plates for making the negatives. These plates are very contrasty and correspond to a process emulsion. Furthermore, they are considered to be "color blind" in the sense they do not give true color values in black and white. This finished plate is a negative and may be used by contact printing to produce a print or, better yet, an enlargement. These enlargements are easily made by cutting a cardboard or plywood carrier to fit in place of the usual 35 mm. film carrier (Fig. 1B). There is a minimum of grain present in the lantern slide emulsion and enlargements of a number of diameters are possible (Fig. 3). Lantern slide positives may be prepared by contact printing on 2 by 2 inch slides, or by enlargement on the standard 3¼ by 4 inch lantern slides.

In taking photomicrographs by the method discussed, the size of the field encompassed is limited. With this in mind experiments were made to find a practical solution for getting around this difficulty. It was solved in the following manner:

A 35 mm. enlarger was used with a cardboard carrier cut so as to enclose in the insertion a standard glass slide, 1 by 3 inches, on which was mounted the tissue section. One can insert the carrier with the slide in the enlarger and project the entire image of the section on a 2 by 2 inch or a 3¼ by 4 inch lantern slide as a negative. No filters are necessary for an approximate record. However, if panchromatic negative materials and filters are used over the enlarger lens, better color renderings and contrasts will be obtained. Of course, such work must be done in total darkness, or while using a green safelight. The negative in either case should be sharp; by using it as outlined excellent prints may be obtained. This approximates very low power photomicrography in an extremely simple manner.

Photomicrographic negatives have been prepared on lantern slide plates from sections stained with hematoxylin-eosin, polychrome methylene blue, and

Masson's trichrome stain. Each of these methods of staining reproduces satisfactorily, and the use of panchromatic materials and filters has not been found necessary in all cases. In blood films, Wright and Strumia's stains have been used with excellent results.

GENERAL

An extremely interesting and relatively simple method for the coloring of photographs of gross specimens is given by Hopkins.⁷ A red to red-brown color on prints is obtained as follows: solution A, 45 grains of uranium nitrate and 10 ounces of water; solution B, 40 grains of potassium ferrieyanide and 10 ounces of water. Equal volumes of each solution are mixed, and 20 minims of glacial acetic acid are then added to each ounce of the mixture. Prints should be prepared in the usual manner, and thoroughly washed and dried. Artist's gum mastic is applied to all areas in which it is desired of obtaining red. The gum mastic dries rapidly. The print is washed in several changes of distilled water and toned in the solution with the depth of color visually controlled. The prints are then blotted and dried, after which the gum mastic may be removed with alcohol. A satisfactory blue may be added by covering all parts of the print except those which are desired to take the blue color. A solution consisting of the following ingredients is prepared: $\frac{1}{2}$ ounce of 10 per cent solution ferric ammonium, $\frac{1}{2}$ ounce of 10 per cent solution potassium ferrieyanide, and 5 ounces of 10 per cent solution acetic acid. The print is immersed until it assumes a dark greenish-blue color, after which it is washed thoroughly. The blue color is intensified by fixing in a hypo bath, and the gum mastic is then removed with alcohol. This method, though somewhat time-consuming and formidable at first glance, is surprisingly easy after a few trials, and the results are well worth the time expended. This subject is discussed more fully in another article.⁸

SUMMARY

Procedures suitable for routine photography in a clinical laboratory are discussed, and certain technical details are given. A method of preparing photomicrographs is outlined. Its value lies in the simple equipment necessary, the foolproof technique, and the quality of photomicrographs obtained. Attention is called to methods for preparing lantern slides of histologic specimens in color and for preparing prints of gross specimens in color that are suitable for use in one's own laboratory.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

TYPHOID CARRIERS: Soluble Iodophthalein in Treatment of Carriers of Typhoid-Paratyphoid Group, Saphir, W., and Howell, K. M. J. A. M. A. 114: 1988, 1910.

A series of conservative measures, including the use of sulfanilamide, failed to render the stools of a carrier of *Bacterium paratyphosum* A free from these bacilli.

The oral administration of soluble iodophthalein was followed by immediate disappearance of the paratyphoid A bacilli from the stool. Repeated stool examinations extending over a seven months' observation period remained consistently negative for these organisms.

The results of a bacteriologic study in vitro as to the bactericidal action of soluble iodophthalein on the bacilli of the paratyphoid group did not entirely explain the curative action in a human carrier.

SULPHANILAMIDE, Antienzymic Nature of Bacteriostatic Action of, Mellon, R. R., Locke, A. P., and Shinn, L. E. Am. J. M. Sc. 199: 749, 1940.

The free amino group of sulfanilamide when incompletely oxidized becomes poisonous for catalase, as a result of which the toxic hydrogen peroxide produced by many pathogenic organisms is permitted to accumulate in their cultures.

In addition to catalase, other enzymes are adversely affected by the intermediate oxidation products of the sulfonamide compounds. As known so far, they are peroxidase, certain dehydrogenases, and nitrotase. The nutrition of the bacteria is thus seriously affected, and bacteriostasis results.

The effect of such bacteriostasis against pneumococci in vivo is to bring about their "dissociation" into culture phases, whose principal metabolic functions, including hydrogen peroxide formation and virulence, are so critically suppressed that the organisms fall easy prey to the destructive action of the phagocytes.

BRUCELLA, Studies on a Purified Antigen From, Morales-Otero, P., and Gonzalez, L. M. Am. J. M. Sc. 199: 810, 1940.

A method for the preparation of a purified protein derivative from brucella cells is described. The product obtained is of a fine consistency, light brown in color, and of a fairly constant chemical composition; it can be measured accurately and constitutes a good antigen.

The preparation has been used successfully as an antigen in complement fixation tests and in determining cutaneous hypersensitiveness to brucella in man and laboratory animals.

In man there is a direct relationship between contact with infected material or ingestion of infected raw products and skin reaction to purified brucella protein.

The incidence of positive reactors to the skin test in Puerto Rico, where *Br. abortus* infection is prevalent in cattle, was 24.7 per cent in contact groups, and 4.2 per cent in groups from the general population consuming raw milk from infected sources. On the island of St. Thomas, where infection is not known to exist, the authors were unable to find any reactors in the group examined.

The method follows: Large amounts of *Br. abortus* are grown on standard nutrient agar pH 7.8 in Blake bottles for seventy-two hours at 37° C. Approximately 5 ml. of solution with 0.5 per cent phenol are added to each bottle and left for thirty minutes in contact with the culture to loosen the cells. The phenolized saline containing the suspension of cells is removed from the bottles with sterile pipettes, and the surface of the agar is thoroughly

washed with more phenolized saline. The organisms are recovered by centrifuging at high speed, and dried in a calcium chloride desiccator until they attain a horny appearance. Then they are ground in an electric grinding apparatus to obtain a fine white powder. This fine powder is mixed with 2 liters of 0.02 N sodium carbonate and placed in the refrigerator overnight. Next morning the alkaline suspension is filtered, first through a paper and then through a Berkefeld candle. To the filtrate is added 0.5 per cent phenol, to avoid bacterial contamination during the following steps of the procedure. The filtrate is then concentrated by ultrafiltration through alundum cups impregnated with 13 per cent gum-cotton glacial acetic solution, prepared according to the method described by Seibert. The ultrafiltration is continued until the liquid is concentrated to about 100 ml., then it is washed by passing 500 ml. of distilled water through the alundum cup filter. The concentrated colloidal solution is then filtered through a paper to eliminate any insoluble material that may have sedimented during the ultrafiltration. The protein is precipitated by mixing the colloidal solution with one-fourth its volume of a 50 per cent freshly prepared aqueous solution of trichloroacetic acid, making a final concentration of 10 per cent acid. After standing overnight in the icebox, the protein precipitate is thrown down by centrifugation. Then it is washed repeatedly by centrifugation with freshly prepared 10 per cent trichloroacetic acid solution until the washings are colorless. The protein product is then washed with large volumes of anhydrous ether by repeated triturations and centrifugations until all the acid is removed and the precipitate is completely dehydrated. The nitrogen and polysaccharide contents of protein prepared from different batches of cell cultures vary between 1 and 2 per cent.

The final product thus obtained fulfills the requirements, for it is of a fine consistency, light brown in color, and of a fairly constant chemical composition; it can be measured accurately, is stable in the dry state, and constitutes a good antigen. It is not completely soluble in water, but is easily dissolved by adding a few drops of 0.1 N alkali. The solution is neutralized with 0.1 N hydrochloric acid and remains clear. This preparation has been used in determining cutaneous hypersensitiveness among contact groups and groups from the general population of the island of Puerto Rico, where endemic abortion is prevalent, and in the island of St. Thomas, where endemic abortion is not known to exist. At the same time, agglutinative, complement fixation, and opsonocytophagocytic tests were made on the same subjects.

GLUCOSE TOLERANCE, Effect of Large Doses of Insulin on, Appel, J. W., and Hughes, J. Am. J. M. Sc. 199: 829, 1940.

The authors recognize the great value of the glucose tolerance test as usually performed. However, the examination of the urine during the three days following the test appears to be even more useful in determining the actual carbohydrate tolerance. In the cases reported the usual tests would have indicated either more insulin or less carbohydrate, though further examinations as described showed that neither step was indicated.

Two of the cases examined over several weeks showed subjective and objective clinical improvement. Thus it would seem that the authors' procedure could be employed to advantage where more carbohydrate is desirable but more insulin is contraindicated. A simple glucose tolerance test without blood sugar estimations but with recordings of the twenty-four hour urinary glucose over a period of several days before and after the test will indicate whether a given case can utilize additional carbohydrate.

The authors believe that many diabetic persons would benefit from the procedure herein described.

TUBERCLE BACILLI, Effect of Egg Oil on, Steenken, W., Jr. Am. Rev. Tuberc. 42: 422, 1940.

The experiments reported demonstrate that the tubercle bacillus will propagate in egg oil and that the resulting colonies will be smooth and creamy. They also show that this smooth appearance will be manifested by both dissociated variants and by undissociated cultures, and that the resulting colonies cannot be differentiated from one another.

These smooth colonies retain their altered appearance only while they are growing in the presence of the egg oil. Since this occurs regardless of the pH of the medium, the process cannot be a true dissociation; the smooth form of the colony is merely a physical effect of the oil upon its contours.

BLOOD, A New Test for, and Its Application to the Micro-Determination of Hemoglobin, Barrett, J. F. Brit. J. Exper. Path. 21: 22, 1940.

The reduced form of the oxidation reduction indicator 2, 6-dichlorophenol indophenol is a useful reagent for the detection of blood. In the presence of hydrogen peroxide and blood pigment a red color is produced. A response is obtained with a 1:50,000 dilution of blood.

The reaction has been utilized to determine the hemoglobin content of minute quantities of blood. The equivalent of 0.00025 ml. is required for a determination.

The method for hemoglobin determination follows:

Reagents.—(a) 0.2 per cent alcoholic hydrogen peroxide. Add 0.5 ml. of 30 per cent hydrogen peroxide (perhydrol) to 75 ml. alcohol.

(b) Reduced indicator solution. Mix 0.2 Gm. of 2, 6-dichlorophenol indophenol with 120 ml. of glacial acetic acid. Add 25 ml. of 1 per cent stannous chloride solution ($\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$) in 20 per cent acetic acid. Stir until the dye dissolves, warming slightly if the dye is granular. Finally add 20 Gm. of crystalline sodium acetate dissolved in 50 ml. of water. Store the reagent in a dark stoppered bottle.

(c) Stock hemoglobin solution. Determine the hemoglobin content of a sample of normal blood by the oxygen capacity method of Van Slyke and Neill (1924). Dilute the blood with 25 per cent alcohol to give a solution of hemoglobin containing 1.3 Gm. per 100 ml. Store the solution in a stoppered bottle in the refrigerator.

Test for Blood.—Place 5 ml. of the specimen in a clean test tube, add 2 ml. of glacial acetic acid and boil the mixture thoroughly. Cool the tube to room temperature and add 5 ml. of ether. Extract the blood pigment by inverting the tube about twelve times. Place 5 to 10 drops of reduced indicator solution in a second test tube, and add 2 to 3 ml. of alcoholic hydrogen peroxide. Transfer 1 to 2 ml. of ethereal extract from the first test tube to the mixture of reduced dye and hydrogen peroxide in the second test tube. A rose-red color develops in the presence of blood. If no color appears in two minutes, the test is negative.

Microdetermination of Hemoglobin.—Dilute the well-mixed specimen of blood 2,000 times with water, using a carefully calibrated pipette. Prepare a working standard solution of hemoglobin by diluting the stock 1.3 per cent hemoglobin solution 200 times with water, e.g. 0.5 ml. to 100 ml.

Pipette 2 ml. of the reduced indicator solution into two test tubes labeled "standard" and "unknown." Add 2 ml. of the alcoholic hydrogen peroxide and mix thoroughly, making sure that no hydrogen peroxide is left on the sides. Add 0.5 ml. of the standard and immediately afterwards 0.5 ml. of the unknown solution of hemoglobin to the appropriate tubes and mix thoroughly. After one hour add 10 ml. of water to each tube, inverting several times to mix the contents. Compare the unknown with the standard in the colorimeter, using a green glass light filter to facilitate the matching.

Calculation: $\frac{\text{Reading of Standard}}{\text{Reading of Unknown}} \times 13 = \text{Grams of hemoglobin per 100 ml. blood}$

When a blood low in hemoglobin is encountered, a more suitable dilution, e.g. 1:1,000 or 1:500, should be made.

LEUKOCYTOSIS, On the Mechanism of, With Inflammation, Menkin, V. Am. J. Path. 16: 13, 1940.

Leukotaxine, a crystalline nitrogenous substance recovered from inflammatory exudates, and known to increase capillary permeability and cause diapedesis of polymorphonuclear leucocytes, fails to induce an increase in the leucocytic level of the circulation in either the dog or the rabbit. Hence it can scarcely be responsible for the leucocytosis of inflammation.

There is present in exudates a leucocytosis-promoting factor capable of inducing a rise in the leucocyte level of dogs. This is demonstrable when either the whole or the cell-free exudate is introduced into the circulating blood.

An inflammatory exudate removed from an animal with leucopenia and injected into a normal dog fails, as a rule, to induce a marked rise in the leucocyte count.

Blood serum, sterile broth, bacterial cultures of exudates, and cultures of killed bacteria (*Staphylococcus aureus*) are all ineffective in causing an increase in the leucocyte level of the circulation.

Histamine and adenosine are likewise essentially inactive. Extraction of exudates containing the active leucocytosis-promoting factor for histamine, yields an end product incapable of inducing leucocytosis. Nucleic acid injected into the blood stream in large concentration favors, after a considerable latent period, a rise in the number of leucocytes. This delayed effect differs from the prompt response induced by exudates.

The action of the leucocytosis-promoting factor seems to be primarily on the bone marrow, producing an outpouring of immature granulocytes into the circulation. The factor is thermolabile. Heating the exudate to 60° C. inactivates the material. The factor, after prolonged dialysis of the exudate through a cellophane membrane, is found to be, in large part, indiffusible. Further studies are now in progress in an endeavor to identify the nature of the leucocytosis-promoting factor present in inflammatory exudates.

PNEUMONIA in Infants and Children, Pneumococcus Typing in, Bullowa, J. G. M., and Simon, H. Am. J. Dis. Child. 60: 256, 1940.

With the method of pharyngeal evacuation applied to a mummied infant and accomplished by the use of a suction bulb with catheter and trap, pulmonary mucus obtained for typing pneumococci gave a type in 95 per cent of cases. The portable apparatus for evacuation is simple to prepare and use.

The apparatus consists of a No. 18 French rubber catheter, with an opening at the end. The catheter is attached to a fire-polished and annealed pyrex glass trap about 4 inches (10.16 cm.) long. From the glass trap through pressure rubber tubing, the catheter is attached by brass tubing to a sputum bottle stoppered with a No. 5 rubber stopper containing two holes. The outlet from the sputum bottle, also of brass, leads to a double action rubber bulb or to an electric suction pump. The pump is of the rotary compressor type, operated by a $\frac{1}{30}$ horse power universal motor.

INFECTION, A Ward Study for Sources of, Long, A. P., McKhann, C. F., and Cheney, L. L. Am. J. Dis. Child. 60: 322, 1940.

A direct, concurrent study of hospital infections in an infants' hospital confirmed the findings derived from an earlier survey of the records of the same institution.

Infections of the respiratory tract accounted for 63 per cent of the hospital infections which were acquired by over 10 per cent of the patients admitted. Most of the secondary infections occurred in very young, premature, malnourished, or debilitated infants who had been in the hospital for several weeks.

Acute infections of the respiratory tract, including pneumonia, present among the patients on admission as well as similar infections and carrier states among the staff, attendants, and visitors, were the great source of danger.

Examinations for new nasopharyngeal bacterial invaders in secondarily infected patients indicated the source of most of the infections to be hospital personnel and visitors rather than fellow patients.

Overcrowding in connection with hospital-acquired infections should be considered, with the term "overcrowding" applied not only to patients but also to the large numbers of persons other than patients who are permitted to enter the wards.

Some diminution in the transmission of organisms followed masking of all persons entering the ward. Masking, even with a special type of mask, was insufficient to eliminate secondary infections.

TISSUE: Rapid Method of Staining Gram-Positive Organisms in Frozen Sections
Krajian, A. Arch. Path. 30: 614, 1940.

Method.—

1. Fix tissues in a 10 per cent solution of formaldehyde for twenty-four hours or longer.
 2. Cut thin frozen sections.
 3. Transfer the section to a glass slide.
 4. Drain and dehydrate immediately with absolute alcohol or anhydrous isopropanol.
- Blow on the section until all the alcohol is evaporated.
5. Blot dry.
 6. Dip twice in thin celloidin (a pyroxylin preparation). Blow on the section and dip in water.
 7. Stain with Sterling's gentian violet for two minutes.
 8. Rinse in water and apply Gram's iodine solution for two minutes.
 9. Blot completely dry.
 10. Flood the section with eosinol (with medicine dropper) and agitate the slide. Generally one or two applications are sufficient to remove the gentian violet and at the same time counterstain the section red.
 11. Treat with carbolxylene for thirty seconds.
 12. Treat with two changes of pure xylene, fifteen seconds each.
 13. Mount in gum dammar.

Results: Gram-positive organisms (bacteria and fungi) are stained violet; gram-negative organisms are unstained; the background is bright red.

For emergency examination, fresh tissues are fixed as follows:

A 10 per cent formaldehyde solution is brought to a boil, and thin blocks of tissue are dropped into it. The container is placed in a paraffin oven at 56° to 60° C. for fifteen minutes' fixation. Then frozen sections are prepared and stained as already described.

Preparation of Eosinol.—Dissolve 5 Gm. of aqueous eosin in 10 c.c. of distilled water. Precipitate it by adding 10 c.c. of glacial acetic acid and 2 c.c. of concentrated hydrochloric acid, and mix with a glass rod.

Incubate the resulting coagulum at 56° C. for from twelve to sixteen hours, or until the water has evaporated.

Dissolve this dehydrated acid eosin in 10 c.c. of absolute alcohol or anhydrous isopropanol and 20 c.c. of acetone, stirring with a glass rod for several minutes and placing in a paraffin oven for two hours. Let the undissolved portion, which is to be discarded, settle to the bottom of the container. Remove the clear portion with a clean, dry pipette, add to 1,500 c.c. of carbolxylene (1 part of pure phenol crystals in 3 parts of neutral xylene). Some precipitate will form, which will settle to the bottom of the container. The clear portion is eosinol. The solution keeps indefinitely.

Owing to the variation in the staining power of various brands of powdered eosin, it may be necessary to standardize the solution by staining control sections and adjusting the strength of the eosinol by reducing or increasing the amount of carbolxylene.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vnuglian, Professional Building, Richmond, Va.

Poisons, Their Isolation and Identification*

AS NOTED in the Foreword, the number of poisoning cases in Egypt is sufficiently large to engage permanently a force of chemists in the necessary medicolegal determinations. This book, written by the late Director of the Medicolegal Laboratory of the Ministry of Justice is, therefore, based upon an extensive and comprehensive experience.

Each procedure detailed has been personally used and found reliable by the author. The book is hence a record of practical experience and as such should prove of great value to others engaged in this field.

The author presents in Chapter X a systematic scheme for the identification of alkaloids embodying much that is original. A complete author index and a comprehensive general index make the contents of the book readily available.

Intended as a practical manual for all chemists who have to deal with poisoning cases, this book should fill a definite need.

The Complete Pediatrician†

THE necessity for a third edition in six years is ample testimony to the practical clinical utility of this book. Comprehensive and well organized, it embodies perhaps the most complete epitome in small compass of pediatrics yet available.

It can be consulted with confidence that the information sought will be found and that when found it will be in readily applicable form.

This new and revised edition should prove as welcome and as useful to the clinician as did its predecessors.

The Essentials of Applied Medical Laboratory Technic‡

A PROFUSELY illustrated volume describing the generally accepted routines in clinical laboratory work, this book should be of especial value for the clinical pathologist's assistant and can be very highly recommended to all technicians. Indeed, it will probably become a widely used textbook for technicians.

Embalming Fluids§

A COMPREHENSIVE discussion of the art of embalming from the earliest to the present time, this book contains much information of interest, not only to embalmers, but also to physicians and pathologists and all who are interested in the historical aspects of this subject.

*Poisons, Their Isolation and Identification. By Frank Bamford, B.S., late Director of Medicolegal Laboratory, Ministry of Justice, Cairo, Egypt. With Foreword by Sydney Smith, M.D., F.R.C.P. Washable binding, 344 pages, 21 illustrations, \$4.00. P. Blakiston's Son & Co., Philadelphia, Pa.

†The Complete Pediatrician. Practical, Diagnostic, Therapeutic, and Preventive Pediatrics. By W. C. Davison, M.D., Professor of Pediatrics, Duke University School of Medicine. Cloth, ed. 3, 256 pages, \$4.00. Duke University Press, Durham, N. C.

‡The Essentials of Applied Medical Laboratory Technic. Details of How to Build and Conduct a Laboratory in Hospital or Office at Small Cost. By J. M. Feder, M.D., Director of Laboratories and Allergic Service, Anderson County Hospital, Anderson, S. C., Cloth, 234 pages, profusely illustrated, two plates in color, \$5.00. Charlotte Medical Press, Charlotte, N. C., 1940.

§Embalming Fluids. Their Historical Development and Formulation From the Standpoint of the Chemical Aspects of the Scientific Art of Preserving Human Remains. By Simon Mendelsohn, F.A.I.C., Consulting Chemist. Cloth, 166 pages, 6 figures and frontispiece, \$4.00. The Chemical Publishing Co., New York, N. Y.

Histopathology of the Peripheral and Central Nervous Systems*

HERE is a volume that should always be available as a companion piece to any text on clinical neurology. Its function is similar to that of the texts of general pathology in relation to texts on general medicine. It is very complete, with discussion of very recent studies, including the many forms of meningitis and encephalitis and the myopathies.

The book is abundantly and well illustrated.

Laboratory Text in Pharmacology†

THIS excellent manual of experimental exercises is intended to serve as a supplement to the more complete texts. It was developed over the course of several years; hence it has been subjected to the vicissitudes of actual laboratory use.

Valuable tips are given as to the proper technique of administering drugs to various mammals. The reviewer can recall a ruined experiment which would have had better results had he been forewarned "that rabbits are very adept at kicking syringes and bottles off the table."

The second portion of the book deals with prescription writing and materia medica, the former of which gives evidence of becoming a lost art under the pressure of commercial preparations. Throughout, frequent references are given to the current literature.

The manual can be highly recommended.

Pathological Histology‡

THE student of pathology and the physician looking for a "refresher" course will find this a text of outstanding value for the purpose. The pathologist, too, will find it a valuable addition to his reference library.

The text is succinct and authoritative. The numerous illustrations—Fialay-process transparencies of excellent quality excellently reproduced—are well chosen and worthy of the highest commendation. They are, indeed, an outstanding feature of the book which can be highly recommended without reserve. Altogether an excellent "buy," it is moderately priced and well worth its cost.

Erratum

On page 730 of the January number of the JOURNAL in the article by Ida Kraus, Ph.D., and Sol Dulkan, B.S., entitled "The Determination of Hippuric Acid in Urine," the eleventh line of the paragraph below Table I should read "ten normal sulfuric acid" instead of "tenth normal sulfuric acid." On page 731 the seventh line of the second paragraph below Table II should read "10 normal sulfuric acid" instead of "1:1 sulfuric acid."

CLINICAL AND EXPERIMENTAL

THE DIAGNOSTIC VALUE OF THE TAKATA-ARA REACTION IN THE CEREBROSPINAL FLUID*

PAUL B. SZANTO, M.D., AND SAMUEL BURACK, M.D., KANKAKEE, ILL.

LABORATORY tests devised for the examination of the cerebrospinal fluid are numerous. Despite this we agree with Kafka¹ that investigation of proteins in cerebrospinal fluid opens up new fields of research, particularly in the albumin-globulin relationship.

Eskuchen² stressed the importance of the different colloidal and protein reactions, the proteins (albumin and globulin) varying in their sensitivity to the various reagents. He introduced the term "protein spectrum." We must also consider the statement of Kafka³ that pathologic processes result not only in quantitative change of the globulin and albumin and change of the ratio between both, but also qualitative alteration of the proteins themselves.

In 1925 Takata and Ara⁴ introduced a new serum colloid test for differentiation between lobar and bronchopneumonia. In the same year they⁵ used the test for examination of the cerebrospinal fluid to differentiate between bacterial meningitis and syphilis of the central nervous system.

The reaction is based on the following: If a solution of mercuric chloride is mixed with sodium carbonate in the presence of a protein colloidal system, for example, spinal fluid, there results a colloidal solution (HgO). The addition of fuchsin solution results in the formation of a violet blue color because the fuchsin is adsorbed by the colloid (HgO). In syphilitic spinal fluid there occurs a precipitation of the colloids with a resulting violet blue to blue color. Spinal fluid of bacterial meningitis gives a red color with little or no precipitation. Normal spinal fluid gives a violet blue color with no precipitation.

In 1929 Staub⁶ and Jezler⁷ introduced the Takata-Ara serum test for the diagnosis of parenchymatous liver diseases, especially for the diagnosis of liver

*From the Kankakee State Hospital, Kankakee. Dr. G. W. Morrow, Managing Officer.
Received for publication, March 4, 1940.

cirrrosis. In the following years many investigators (Staub,⁸ Skouge,⁹ Schindel and Barth,¹⁰ Takata,¹¹ Kirk,¹² and Fulde¹³) affirmed the diagnostic value of this test for hepatic cirrhosis.

The reports of Takata and Ara on the cerebrospinal fluid in central nervous system syphilis were confirmed for the most part by various workers.

Münzer¹⁴ examined 100 persons, of whom 30 had general paresis. These 30 gave the paretic type of Takata reaction, while the bacterial meningitis patients did not give consistent results. In those with paresis there was a parallelism between the Takata and Lange tests.

Nicole¹⁵ found the Takata test more sensitive than the Ross-Jones, Weichbrodt, and Nonne-Apelt tests. He stated that the test was not specific for bacterial meningitis. Blum,¹⁶ Cameron and McCulloch,¹⁷ and Monias¹⁸ reported similar findings.

Walton¹⁹ examined 350 spinal fluids and found a parallelism between the Takata test and the Lange and mastie tests. He also stated the test was not specific for bacterial meningitis. All the workers mentioned followed more or less the original technique of Takata and Ara. Ueko²⁰ modified the Takata blood serum test, and this modification was applied to the spinal fluid by Fleischhaecker.²¹ Ornstein used the same modification, and both he and Fleischhaecker affirmed the diagnostic value of the modified Takata-Ara reaction for neurosyphilis.

We felt it would be worth while to evaluate the results of the Takata-Ara test for the following reasons: First, we wished to prove the specificity of the test as originally described by Takata and Ara. Our material did not lend itself to evaluation of the specificity of the test for bacterial meningitis. Second, we wished to compare the diagnostic value of the test in relation to other routine cerebrospinal fluid determinations. Third, we wished to see which modification gave best results from the standpoint of both simplicity and sensitivity. Finally, we attempted to reach a better understanding of the mechanism behind the test.

TECHNIQUE AND INTERPRETATION

The Takata-Ara reaction can be performed in two ways: (1) the original five-tube method and (2) the so-called one-tube method. In the original technique, 1 c.c. of 0.3 per cent sodium chloride solution is added to four of five Wassermann test tubes. One cubic centimeter of spinal fluid is placed in the first and second tubes. The second tube is well agitated, and 1 c.c. of the mixture is added to the third tube, etc. One cubic centimeter from the fifth tube is discarded. One drop of 10 per cent sodium carbonate solution is added to each tube, followed by 0.3 c.c. of the Takata reagent. The Takata reagent consists of 0.5 per cent mercuric chloride and 0.02 per cent fuchsine solution in equal amounts. The tubes are well shaken and left at room temperature. The results are read after five, fifteen, and thirty minutes, and again after twenty-four hours. If the precipitation occurs immediately, or within a few minutes, we have a three-plus reaction; if the precipitation is complete after fifteen minutes, the reaction is two plus; after thirty minutes, one plus; and after twenty-four hours, one plus. The results were plotted on a curve. Spinal fluid from neurosyphilis gives complete precipitation in a short time.

In the one-tube method Ueko's modification was applied, wherein fuchsin solution is not used. The reagents required are 10 per cent anhydrous sodium carbonate and 0.5 per cent mercuric chloride solution. One cubic centimeter of spinal fluid is placed in a Wassermann tube to which is added one drop of the sodium carbonate solution and 0.1 c.c. of mercuric chloride solution. The exact amount of sodium carbonate used is very important because this substance influences the pH of the entire colloidal system. Glasoe and Sorum²² showed that the sensitivity of a gold sol in the Lange spinal fluid test for paresis increases with an increase in the particle size, and decreases with an increase in the pH. We were able to show that the same principle applies to the Takata-Ara test. The results are read immediately, then after five, fifteen, thirty, sixty, and ninety minutes.

The interpretation of the results in the one-tube method is as follows: Three plus is indicated when flocculation occurs immediately with sedimentation. In a two-plus reaction complete flocculation and sedimentation occur in from five to thirty minutes. A one-plus reaction is indicated when an opacity occurs within thirty minutes. The reaction is negative when the mixture remains clear, or when there is a very slight opacity after thirty minutes.

At first we used both methods. However, we soon saw that our results with the one-tube method were as accurate as with the five-tube method.

MATERIAL AND RESULTS

We examined 314 persons. Of these there were 167 with general paresis, treated and untreated. Many of the treated patients had completely negative routine laboratory findings. In addition we had 147 individuals without paresis, 54 with dementia praecox, 40 with chronic alcoholism, 8 with idiopathic epilepsy, 9 with mental deficiency, 4 with psychoneurosis, 1 with pachymeningitis hemorrhagica interna, 1 with multiple sclerosis, 2 with manic-depressive psychosis, 15 with cerebral arteriosclerosis, 12 without psychosis, and 1 with traumatic psychosis.

GENERAL PARESIS

Our group of patients with general paresis had been on treatment for a number of years and some of them had resultant negative serologic and spinal fluid findings.

Of the 167 cases there were 34 with three-plus Takata reaction. In every case the spinal Wassermann was strongly positive. The Ross-Jones test gave a positive result in 19 cases, a trace in 10, and a negative result in 5. The cell count was less than ten in 11 cases, between ten and fifty in 14, and over fifty in 9. The gold sol reaction was in the first zone in 32 cases, and in the middle zone in 2.

There were 13 cases of two-plus Takata reaction. The spinal Wassermann was positive in every case. The Ross-Jones test was positive in 4, showed a trace in 7, and was negative in 2. The cell count was less than ten in 4 cases, between ten and fifty in 7, and over fifty in 2. The gold sol reaction was in the first zone in 7 cases, and in the middle zone in 6.

Sixty-seven persons gave a one-plus Takata reaction. The spinal Wassermann was positive in 64 and negative in 3. The Ross-Jones test was positive

in 2, showed a trace in 23, and was negative in 42. The cell count was less than ten in 49, between ten and fifty in 15, and over fifty in 3. The gold sol reaction was in the first zone in 1 case, in the middle zone in 32, in the end zone in 32, and negative in 2 cases.

There were 53 persons with negative Takata reaction. The spinal Wassermann was positive in 13 and negative in 40. The Ross-Jones test showed a trace in 2, and was negative in 51. The cell count was less than ten in 52 cases and between ten and fifty in 1. The gold sol reaction was in the first zone in 1 case and in the end zone in 3; there was none in the middle zone, and 49 cases were negative.

In the 147 persons without paresis the Takata reaction was negative.

The Takata-Ara reaction resembles the Weichbrodt test in that it utilizes mercuric chloride. However, there is a striking difference in the results. In the Weichbrodt test 0.3 c.c. of 1:2,000 mercuric chloride solution is added to 0.7 c.c. of spinal fluid in a test tube. A positive test is indicated by flocculation or opacity. We performed this test in 49 patients. In 31 both Takata-Ara and Weichbrodt tests were negative; in 18 the Takata-Ara reaction was positive and the Weichbrodt test was negative.

COMMENT

Our results indicate a striking parallelism between the Takata reaction and the gold sol reaction. Of the 114 persons with general paresis with positive Takata reaction the gold sol reaction was negative in only two. Of the 53 persons with general paresis with negative Takata reaction the gold sol reaction was positive in only 4. In addition, the degree of the Takata reaction shows a parallelism with the gold sol curve. The Takata reaction is much more sensitive than the Ross-Jones test. Of the 114 persons with positive Takata reaction the Ross-Jones test was negative in 49 cases, or 44 per cent. In regard to the cell count there is no parallelism.

100 EAST JEFFERY STREET

EPINEPHRINE SECRETION FROM THE ADRENAL GLANDS IN RELATION TO PARATHYROID ACTIVITY*

J. M. ROGOFF, M.D., Sc.D., AND GEORGE N. STEWART, M.S., PITTSBURGH, PA., AND
RUTH CORTELL, Ph.D., CHICAGO, ILL.

IN AN earlier study¹ it was shown that the rate of liberation of epinephrine from the adrenal glands in dogs with experimental hyperthyroidism is not different from that in normal, control animals. Experiments on hypothyroidism, induced by extirpation of the thyroids, may be complicated by possible effects of concurrent hypoparathyroidism. Experiments on thyroparathyroidectomized animals, therefore, have been included in this report.

Probability of functional interrelationship between the parathyroids and the adrenals is suggested from certain earlier observations.² The evidence indicates that such an interrelationship is probably concerned with the function of the adrenal cortex, but it does not exclude the possibility that the medulla may play a significant role in the phenomena observed.

Rogoff and Stewart³ found that adrenalectomized dogs develop symptoms that are commonly associated with disturbances in parathyroid function. Muscular twitching, spasms, and tetanic convulsions often occur. Furthermore, bilateral adrenalectomy is commonly followed by an increase in calcium content of the blood.⁴ At autopsy severe congestion and hemorrhages are found in the alimentary canal of adrenalectomized dogs, similar to that observed by Collip⁵ in unoperated dogs following administration of large amounts of parathyroid extract.

*From the Physiological Laboratory, University of Chicago, and the Laboratory of Experimental Endocrinology,† School of Medicine, University of Pittsburgh.

†Supported by the G. N. Stewart Memorial Fund, founded by contributions from the Lutz D. Beaumont Trust, N. L. Dauby, Mrs. Frances W. Lang, and Howard E. Wise.

Received for publication, March 5, 1940.

The changes that occur in the blood and the disturbances in the alimentary canal that are found during acute adrenal insufficiency in adrenalectomized dogs have been observed in animals with subacute and chronic adrenal insufficiency created by the method described by Rogoff.⁶ In these animals, as well as in those surviving bilateral adrenalectomy without treatment nearly or up to a fortnight, it has been observed that there is a relatively high incidence of parathyroid enlargement.² Some of the blood changes that occur in these animals are the same as those caused by administration of parathyroid extract.

Certain changes that occur in the rat incisor following bilateral adrenalectomy were found by Schour and Rogoff⁷ to be similar to the disturbances in calcification of the dentine observed by Schour, Tweedy, and McJunkin⁸ following administration of parathyroid extract. The rat incisor as an indicator for changes in calcium metabolism is suggested from the sensitive response to parathyroidectomy observed by Erdheim.⁹

The foregoing experimental evidence points to a probable adrenal-parathyroid interrelationship. It appears that the adrenal cortex is concerned with this possible interrelationship. Experimental data concerning the adrenal medulla in relation to parathyroid function is less convincing. Some observations on the pharmacodynamics of epinephrine suggest a possible influence on calcium metabolism. However, unless such observations are quantitatively related to amounts of epinephrine that the adrenals are known to be capable of liberating, they may be misleading. Mathien and Baer¹⁰ failed to obtain a significant effect on the blood calcium of dogs with parathyroid insufficiency when they administered physiologic quantities of epinephrine.

Some investigators have found a reduction in the epinephrine content of the adrenals in animals with parathyroid insufficiency,^{11, 12} while others observed no change.¹³⁻¹⁵ Of course, the amount of epinephrine stored in the adrenal cannot indicate the rate of its liberation; it can represent no more than the balance between production and liberation. However, these conflicting results suggest the possibility that thyroparathyroidectomy sometimes may lead to disturbances which interfere with storage of epinephrine in the adrenals. These disturbances may not develop in all thyroparathyroidectomized animals. This suggestion might be offered in explanation of similar observations regarding the rate of epinephrine secretion reported in this article.

Indirect evidence has been offered in support of the view that certain manifestations of parathyroid insufficiency are associated with a corresponding increase in circulating epinephrine.¹⁶ Czarnecki and Sarabia¹⁷ found no evidence of increased liberation of epinephrine from the adrenals in dogs with parathyroid insufficiency, and Georgopolous obtained negative results with peripheral blood of rabbits. These investigators did not make quantitative determinations of the rate of output of epinephrine from the adrenals.

Our investigation is concerned with the question whether experimental hypoparathyroidism or hyperparathyroidism is associated with a detectable change in the rate of liberation of epinephrine from the adrenal glands. Hyperparathyroidism was induced by administration of parathyroid extract,* and

*Generously supplied by Eli Lilly and Company.

hypoparathyroidism by thyroparathyroidectomy which, of course, includes any possible influence that might result from loss of the thyroid.

The characteristic manifestations of hypothyroidism are not readily obtained in adult dogs following thyroidectomy. This is generally attributed to the presence of accessory thyroid tissue or to incomplete removal of the thyroids. However, definite manifestations of hypothyroidism can be induced by complete thyroidectomy in young dogs if sufficient parathyroid tissue remains to prevent the complications of parathyroid deficiency. It may be assumed also that complete thyroidectomy in older dogs might be associated with some physiologic disturbances that are not as yet recognized.

THYROPARATHYROIDECTOMY

Thyroparathyroidectomy was performed on 11 dogs (Table I) and 11 cats (Table II). Quantitative determination of the rate of liberation of epinephrine from the adrenals was made by the method of Stewart and Rogoff.¹⁵ The epinephrine output from the adrenals was determined at periods ranging between two and thirty days after thyroparathyroidectomy in the dogs, and between two and fifty days in the cats.

In the cat (2-41) on which determination of the epinephrine output was made fifty days after thyroparathyroidectomy, moderate symptoms were present during about half of the experimental period. The symptoms then gradually subsided. One cat (2-33) was thyroparathyroidectomized during advanced pregnancy. Marked tetany developed on the second day after the operation, indicating that the parathyroids of the fetuses did not protect the mother. That fetal endocrine organs do not function in place of the corresponding maternal organs when extirpated was found in the case of the adrenal (Stewart and Rogoff) and in recent observations (unpublished) in case of the pancreas.

Manifestations of parathyroid deficiency, ranging from apathy and mild muscular twitchings to severe convulsive seizures, were present in nearly all animals at the time when they were sacrificed for determination of the epinephrine output. In 8 of the dogs total calcium was determined in the blood serum by the Clark and Collip modification of the Kramer-Tisdall method.¹⁹ As shown in Table I, a decided reduction in serum calcium occurred in all animals. Some of the dogs received parathyroid extract or calcium therapy to control severe symptoms. In these cases the therapy was discontinued to permit the symptoms to reappear before the animal was used for determination of the epinephrine output. In the cats and in four of the dogs no therapeutic measures were employed.

Dog 21 developed symptoms of parathyroid insufficiency eight days after thyroparathyroidectomy. Calcium lactate (10 Gm. daily) was administered for eighteen days thereafter and was discontinued four days prior to determination of the epinephrine output. The symptoms were controlled by the calcium therapy and reappeared when therapy was discontinued. Clonic convulsions were present when the animal was sacrificed for determination of the epinephrine output.

In Dog 69 tetany developed on the fourth day after thyroparathyroidectomy. Calcium gluconate (10 c.c. of 10 per cent solution), which controlled the symptoms, was administered intravenously. Three days later the symptoms reappeared and the animal was sacrificed the following day for determination of the epinephrine output, without receiving any further treatment.

Dogs 61 and 62, both young, developed tetany on the second day following thyroparathyroidectomy. Each dog received 50 units of parathyroid extract. The symptoms were controlled, and Dog 61 was sacrificed the following day for determination of the epinephrine output. Dog 62 developed violent convulsions on the fifth day, and 30 units of parathyroid extract was administered. Determination of the epinephrine output was made the following day.

Dog 71 had tetany on the second day after thyroparathyroidectomy. He received 100 units of parathyroid extract and the symptoms were relieved. Four days later, when the symptoms were again in evidence, the epinephrine output from the adrenals was determined.

Dogs 38 and 74 developed severe tetany on the third and second day, respectively, following thyroparathyroidectomy. Determination of the epinephrine output from the adrenals was then made, without resorting to therapeutic measures.

Dog 68 developed mild tetany on the fourth day and it was present on the sixth day when determination of the epinephrine output was made. Mild tetany developed in Dog 73 on the fifth day following thyroparathyroidectomy, when the animal was sacrificed for determination of the epinephrine output from the adrenals.

HYPERPARATHYROIDISM

Ten dogs were subjected to the influence of parathyroid extract for periods ranging between one and fourteen days (Table III). In all cases a marked

elevation of the level of total calcium in the blood existed at the time when the animals were sacrificed for determination of the epinephrine output from the adrenals.

TABLE III

EPINEPHRINE OUTPUT IN DOGS WITH EXPERIMENTAL HYPERPARATHYROIDISM

RECORD NUMBER	SEX	BODY WEIGHT (KG.)		SERUM CALCIUM PER 100 C.C. (MG.)		COMBINED WEIGHT OF THYROID (GM.)	ADRENAL WEIGHT (GM.)		EPINEPHRINE OUTPUT PER MINUTE (MG.)	
		INITIAL	FINAL	INITIAL	FINAL		RIGHT	LEFT	PER ANIMAL	PER KG.

60	M	7.8	7.3	10.25	19.03	0.90	0.70	0.70	0.00204	0.00025

Dog 41 received 300 units of parathyroid extract in the morning and 200 units in the afternoon of the same day. Epinephrine output was determined eighteen hours after the last injection of parathyroid extract.

Dog 43 received 220 units of parathyroid extract on the first day, 250 units the next day, and 100 units on the third day. Epinephrine output was determined eighteen hours after the last injection of parathyroid extract.

Dog 44 received 200 units of parathyroid extract in the morning and 200 units in the afternoon of the same day. Epinephrine output was determined seventeen hours after the last injection of parathyroid extract.

Dog 47 received a daily injection of 100 units of parathyroid extract on each of three successive days. Epinephrine output was determined on the fourth day. Parathyroid extract caused considerable vomiting. Severe congestion and hemorrhage in the alimentary canal were found at autopsy.

Dog 48 received 50, 30, 30, 50, and 30 units of parathyroid extract on five consecutive days, respectively. Epinephrine output was determined on the sixth day.

Dog 50 received 50, 50, 50, 100, 100, and 100 units of parathyroid extract on six consecutive days, respectively. Epinephrine output was determined forty-eight hours after the last injection of extract.

Dog 55 received 50 units of parathyroid extract daily except on the sixth and twelfth days. On the thirteenth day 75 units were administered and the epinephrine output was determined on the fourteenth day.

Dog 56 received 50 units of parathyroid extract daily for twelve consecutive days. Epinephrine output was determined on the thirteenth day.

Dog 57 received 50 units of parathyroid extract daily for five consecutive days and 20 units on the sixth day. Epinephrine output was determined forty-eight hours after the last injection of parathyroid extract. A hemorrhagic ulcer was found in the stomach at autopsy. In this animal and in Dog 50 the serum calcium had returned to normal level when epinephrine output was determined.

Dog 60 received two injections of 50 units each of parathyroid extract, seven hours apart, on one day, and 50 units the next day; no parathyroid extract was administered the following four days; then 5 doses of 50 units each were administered during the next thirty hours. Epinephrine output was determined fifteen hours after the last injection of parathyroid extract.

DISCUSSION

In only one animal receiving parathyroid extract (Dog 43) was the rate of liberation of epinephrine from the adrenals found to be outside the range ordinarily occurring in normal animals. In view of the normal output found in the other nine animals, we hesitate to attach significance to the relatively low epinephrine output found in this animal.

None of the thyroparathyroidectomized cats showed significant alteration in the rate of liberation of epinephrine from the adrenals. Among the dogs, however, we found a definite reduction in epinephrine output in three of the eleven experimental animals. Normal rate of liberation was found in the other eight dogs. It appears probable that in some thyroparathyroidectomized dogs conditions may develop which can affect the adrenal medulla. This possibility might explain the conflicting results that have been reported concerning the epinephrine store in the adrenals, previously mentioned.

It is known that existence of accessory parathyroids is not uncommon. The suggestion may be made that such accessories, though functionally inadequate to prevent the usual manifestations of parathyroid deficiency in thyroparathyroidectomized animals, might suffice to prevent reduction of the epinephrine output. This could explain the negative results in the cats and in the 8 dogs that showed normal epinephrine output.

The possible influence of relative deficiency of thyroid, together with parathyroid deficiency occurring in some animals but not in others, may be suggested. In the light of present knowledge, however, this can be no more than mere speculation.

The results of our experiments, while not conclusive, support the existing suggestion of a probable functional interrelationship between the parathyroids and the adrenal medulla. Further investigation is necessary to obtain more unequivocal evidence. However, it appears that under some conditions, the exact nature of which is not known, parathyroid insufficiency can lead to a reduced rate of liberation of epinephrine from the adrenal glands.

SUMMARY

1. Under certain conditions, the nature of which is obscure, parathyroid insufficiency can lead to reduced epinephrine output from the adrenals.
2. Hyperparathyroidism, induced by administration of parathyroid extract, does not appear to influence the rate of epinephrine secretion from the adrenals.

A CASE OF INSULIN ALLERGY SIMULATING CORONARY OCCLUSION*

HARRY F. WECHSLER, M.D., LAURENCE FARMER, M.D., and
JEROME A. URBAN, M.D., NEW YORK, N. Y.

NUMEROUS cases of insulin allergy have been reported in the literature. In the majority of these cases, local or generalized urticaria and angio-neurotic edema dominated the clinical picture. In a smaller number of instances, there were more severe allergic reactions, such as circulatory impairment, gastrointestinal symptoms, pulmonary edema, and collapse. Immunologic studies revealed that the observed hypersensitivity was due either to protein impurities accompanying the insulin or to pure crystalline insulin itself. Passive transfer of the sensitivity was effected in several instances. A comprehensive review of the literature has recently been published by Herzstein and Pollack.¹

The following case of insulin allergy, which followed the general immunologic pattern, presented an interesting, and as far as we know, a not yet described differential diagnostic problem.

A. J., a 65-year-old white woman, was admitted to the Lenox Hill Hospital for the first time on January 6, 1932, for the reduction and immobilization of a fracture of the left radius. She was found to be suffering from diabetes mellitus and was put on a diet and 20 units of insulin (Nletin) daily. She discontinued her diet after one year, but continued to take the 20 units of Nletin.

*From the Medical Service of Dr. Otto M. Schwerdtfeger and the Allergy Clinic of Dr. Laurence Farmer, Lenox Hill Hospital, New York.
Received for publication, March 13, 1940.

She was readmitted to the hospital on July 21, 1936, for an osteomyelitis of the right toe. During her stay at the hospital she was again put on a diet and 20 units of Iletin. She was discharged on September 21, 1936, and told to discontinue her insulin as the diet alone sufficed to control the diabetes. The patient took no insulin until December, 1938, when 5 units were administered because of glycosuria and pruritus vulvae. Ten minutes after this injection she became unconscious, dyspneic, thrashed about, and had a cold sweat. She was given orange juice and completely recovered from the attack in about two hours. Since this episode she has been fearful of taking insulin.

Her third admission to the Lenox Hill Hospital was on April 3, 1939, for an ulcer of the right foot. Physical examination revealed a markedly obese elderly woman who did not appear acutely ill. Her temperature was 100.8° F.; her respirations were 20 per minute. There was no dyspnea or cyanosis. Numerous areas of vitiligo were present in the skin, and on the sole of the right foot was an ulcerated callus.

The pupils were equal, regular, and reacted to light and accommodation. The sclerae were clear. There was no exophthalmos, lagophthalmos, or nystagmus. The skin of the eyelids was loose, redundant, and had a puffy appearance. The conjunctivae were injected.

The mouth was edentulous. The tongue was slightly coated. The tonsils were small and cryptic, and the pharynx was congested.

The lungs were resonant throughout with normal breath sounds. No râles were audible.

The point of maximal impulse of the apex was in the fourth interspace in the mid-clavicular line. The border could not be accurately elicited because of obesity. The second aortic sound was accentuated and somewhat harsh. A systolic murmur was heard over the aortic area and a soft, low-pitched systolic murmur at the apex. The pulses were equal, regular, and the rate was 88. The blood pressure was 170 systolic and 90 diastolic.

No organs or masses were palpable in the abdomen. There was slight ankle and pretibial edema. The dorsalis pedis arterial pulsations were normal bilaterally. The reflexes were equal and active. There were no pathologic reflexes.

COURSE

The fasting blood sugar was 210 mg. per cent, and the urine revealed 1.4 per cent sugar and a trace of acetone. On April 5, 1939, the patient was given 20 units of Iletin in the morning after breakfast. Forty-five minutes after the injection the patient suddenly went into collapse. She complained of dizziness, vomited her breakfast, and was very dyspneic. There was no precordial pain. The skin was pale, cold, and clammy. The heart sounds were feeble and tic-tac in quality. The pulse was imperceptible at the wrist, and the blood pressure could not be obtained. Her venous pressure was 124 mm. The white blood count was 16,000; polymorphonuclear cells 81 per cent, twelve of which were immature; lymphocytes 18 per cent; monocytes 1 per cent.

An electrocardiogram taken fifteen minutes after the onset of the attack showed only minimal changes. These consisted principally of a depression of the S-T interval in Lead I, deep S and an inversion of the T-wave in Lead III, and a small R-wave and flattened T-wave in several of the precordial leads.

The patient was given 200 c.c. of orange juice and one-sixth grain of morphine, and was placed in an oxygen tent. She recovered rapidly and progressively from her shock; twelve hours later her blood pressure was 150 systolic and 100 diastolic; her heart sounds were of good quality and her pulse rate was 84.

Although the cardiologist considered various other possibilities, because of the white count of 16,000, the electrocardiographic changes, the fall in the blood pressure, and the tic-tac heart sounds, he favored the diagnosis of coronary occlusion and advised treating the patient for such. The features which militated against that diagnosis were the rapid recovery from the profound shock, the absence of temperature, and the normal erythrocyte sedimentation rate. In addition, a history was subsequently obtained of a similar attack three years previously following the injection of insulin.

During the next few days her blood pressure fluctuated between 90 systolic and 60 diastolic to 150 systolic and 90 diastolic. On April 6, the fasting blood sugar was 192 mg. per cent. The urine remained sugar free on diet alone, with only occasional slight spilling. The temperature remained normal throughout her stay. There was no increase in the erythrocyte sedimentation rate. Electrocardiograms taken at frequent intervals showed slight and inconclusive changes. These were practically confined to the T-wave in Lead III. The S-T interval returned to the base line the day after the attack.

On May 17, 1939, six weeks after her attack, she was given three units of Iletin after breakfast. Her fasting blood sugar was 132 mg. per cent. Twenty-five minutes later she went into a profound shock. Fifteen minutes after the beginning of this attack the blood sugar was 143 mg. per cent.

Twenty minutes after the beginning of the attack the pulse was barely perceptible and very rapid. The blood pressure was 65 systolic and 0 diastolic. The patient was cyanotic, dyspneic, and exhibited irregular sighing respirations. Her skin was cold, moist, and clammy. She showed tremors and convulsive movements. Adrenalin injected subcutaneously gave her slight relief; she was drowsy for several hours. The blood pressure six hours later was 85 systolic and 65 diastolic. The white blood cell count eight hours later was 9,200. The electrocardiogram shortly after the onset of the attack showed minimal changes. An allergic work-up was done one week later. Table I contains the skin tests.

The patient gave positive reactions to all tested brands of insulin, including crystalline insulin. She did not react to pork, beef, and lamb extracts. These tests show clearly that she was allergic to pure crystalline insulin. Passive transfer was attempted. The result was inconclusive as the normal test person gave positive intradermal reactions also in untreated skin areas.

TABLE I

TEST SUBSTANCE	METHOD OF TESTING		
	SCRATCH	PUNCTURE	INTRADERMAL
Lilly's Iletin 40 U.	+++	+++	
Lilly's Iletin special (Beef) 20 U.	+++	+++	
Squibb's insulin 20 U.	±	+ (+)	
Stearn's insulin	±	+	
Lilly's Iletin zinc 40 U.	++	+ (+)	
Stearn's zinc insulin	++	++	
Lilly's protamine zinc insulin 40 U.	++ (+)	++	0
Pork	0	0	0
Beef	0	0	0
Lamb	0	0	0

SUMMARY

The injection of 20 units, and later of 3 units, of Iletin (Lilly) in a 65-year-old arteriosclerotic hypertensive diabetic patient gave rise to a syndrome strongly simulating coronary occlusion. Reviewing the case from the viewpoint of a possible allergy, it is clear that we are dealing with the symptoms of anaphylactic shock. Skin tests corroborated this assumption.

THE ROLE OF METALS IN CARBOHYDRATE METABOLISM*

ZOLTON T. WIRTSCHAFTER, B.S., M.D., CLEVELAND, OHIO

EXTENSIVE experimental and clinical investigations concerning the effect of various metals-insulin mixtures have been recorded by many workers. Thus, it is well known that the addition of 0.1 per cent of zinc to insulin delays and prolongs the action of the latter, while the addition of 0.9 per cent of zinc completely inhibits the insulin effect. This phenomenon brings up the question of the possible basic role of the metals in carbohydrate metabolism under both physiologic and pathologic conditions. To evaluate the state of our present knowledge the important contributions in this field are summarized.

Sodium.—Magenta¹ studied the effect of sodium fluoride on the glyceemic levels of dogs. He found that the intravenous injection of sodium fluoride did not provoke a glycosuria or a hyperglycemia in them. His observations supplement those previously described by Goldenberg,² who observed a glycosuria among both lambs and horses subjected to prolonged ingestion of sodium fluoride.

In 1925 Abelin and Goldener³ investigated the effect of certain sodium salts on the hypoglycemic action of insulin in animals. The oral administration of 2 Gm. of monosodium phosphate ($\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$) or 2 Gm. of a mixture of sodium chloride, sodium bicarbonate, and sodium sulfate produced a marked augmentation of the hypoglycemic effect of 4 to 6 units of insulin given simultaneously. The use of 2 Gm. of disodium phosphate ($\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$) has no appreciable effect on insulin action (Abelin and Goldener³).

Apparently these authors did not understand nor question the reason why disodium phosphate did not equal or increase the hypoglycemic effect of insulin action. It is clear that they did not take into consideration the twelve times larger amount of water crystallization in the disodium phosphate molecule, thus producing a unit containing much less sodium per gram than monosodium phosphate. It is quite probable that if this fact were taken into account, the effect of the disodium salt would be equal to or greater than that of the monosodium phosphate. The fact that the effect of the sodium salt mixture was equal to that of the monosodium phosphate appears to indicate that the active portion of the molecule is the sodium ion. Abelin and Goldener³ did not determine whether the hypoglycemic effect of the sodium salts is a direct effect on carbohydrate metabolism or merely an indirect result of their effect on insulin.

This problem has been further investigated by McQuarrie, Thompson, and Anderson,⁴ who demonstrated that the hypoglycemic effect of sodium salts is a direct one on carbohydrate metabolism, since a drop in blood sugar level of persons with diabetes could be produced without the simultaneous injection of

*From the Department of Medicine, City Hospital, Western Reserve University, and the Department of Medicine, Mt. Sinai Hospital, Cleveland.
Received for publication, March 11, 1940.

insulin. They also studied the effect of excessive ingestion of sodium salts on the carbohydrate metabolism of four diabetic children, between 13 and 15 years of age. In each case it was found that the ingestion of approximately 60 Gm. of sodium chloride daily produced a marked decrease in the amount of glucose appearing in the urine. In the case of a 15-year-old boy who required 32 units of insulin daily, the administration of 60 Gm. of salt decreased the urinary glucose from 73 Gm. to a minimum of 13 Gm. after two days. After seven days the salt was discontinued and the urinary glucose returned to the original level within three days. Although the fasting blood sugar level was decreased and the respiratory quotient was increased by salt administration, the appearance of the sugar tolerance curve did not show any change. Less insulin was required during the period of salt administration, since typical insulin reactions occurred when the insulin dosage was not decreased. It was shown that the effect was due to the sodium ion, since the use of other sodium salts produced similar effects while other chlorides did not. The administration of excessive amounts of sodium chloride did not produce hypoglycemia in a normal control subject. The mechanism of the sodium action is not known. It does not appear that the phenomenon can be satisfactorily explained solely on the basis of water and glucose retention in the tissues. McQuarrie and associates⁴ investigated the possible importance of cortical extract in explanation of the sodium effect; e.g., after producing a marked decrease in the glycosuria of a person with severe diabetes, these workers substituted adrenal cortical extract for the sodium chloride and found that the degree of glycosuria returned toward the presaline level.

Potassium.—The action of the potassium ion on carbohydrate metabolism is, in general, directly opposed to that of the sodium ion. Potassium chloride, when administered alone, tends to decrease carbohydrate tolerance and to raise the blood sugar level, both in man and experimental animals. As in the case of sodium, the exact mechanism involved is not definitely known. Rathery, Bertoliatti,⁵ and others found that the blood potassium level of diabetic individuals is characteristically elevated. McQuarrie⁴ noted a drop in serum potassium of diabetic persons while on a high sodium chloride intake. The high vegetable diet of the average diabetic person is high in potassium content. McQuarrie⁴ and his co-workers have reported an increase averaging 50 per cent in the excretion of glucose in persons with diabetes while being fed extra amounts of potassium chloride. While receiving 10 to 20 Gm. of potassium chloride, a low sodium diet, and the carbohydrate intake kept constant, the urine glucose excretion increased from 60 to 70 Gm. to 70 to 100 Gm. daily. They found that the oral administration of potassium chloride to a diabetic patient receiving large amounts of sodium chloride resulted in an elevation of the glucose excretion. The results appeared to indicate that the administration of one milliequivalent of potassium neutralized the effect of three milliequivalents of sodium.

The antagonistic effects of sodium and potassium were similar in diabetic persons receiving insulin and those not receiving insulin therapy. McQuarrie and co-workers⁴ report the relief of symptoms due to hypoglycemia in an acromegalic person by the administration of potassium chloride.

Calcium-Magnesium.—Kiyohara, Morita, and Muta⁶ investigated the effect of potassium on the glycemic levels of dogs by means of perfusion of the isolated pancreas with blood to which potassium chloride had been added. The addition

of potassium chloride (0.1 Gm. per 100 c.c. of blood) modified the content of the blood sugar. Kiyohara, Morita, and Muta⁸ stated that the potassium ion did not exercise any direct influence on the insular tissue of the pancreas. Their work clearly showed that in rabbits an injection of 3 c.c. of potassium chloride solution (2 Gm. per 100 c.c. per kilogram of body weight) established a hyperglycemia of such severity that it lasted for ninety minutes. This observation corresponds to the findings of Hochfeld⁷ and others. The injection of 3 c.c. of a solution of calcium chloride (5 parts per 100 c.c. per kilogram of body weight) also provoked a hyperglycemia, but the latter was less accentuated than that caused by potassium chloride. Barath⁸ and Schenk⁹ report a hypoglycemia in the same type of experiment. Previous injection of atropine did not modify the hyperglycemia provoked by the injection of either potassium or calcium. Kiyohara⁸ found that the hyperglycemia could not be induced by either potassium or calcium ions after the extirpation of both adrenals as it could before the extirpation. Kiyohara⁸ attributed the hyperglycemia brought about by these ions to the action on the adrenals themselves. Hazard¹⁰ studied the action of calcium and magnesium on potassium-provoked hypertension and hyperglycemia. He demonstrated that large doses of potassium chloride cause a discharge of adrenalin, which in turn produces a hypertension and a hyperglycemia. He showed that magnesium prevents potassium from exercising its adrenalin action while calcium allows it to provoke the adrenalin discharge but diminishes its hyperglycemic effect. The reduction of adrenalin glycosuria by calcium has been noted by various authors, some of whom even advocate the use of calcium salts in the treatment of diabetes in man. Among these, Asada¹¹ has shown that, in rabbits, repeated intravenous injections of small amounts of calcium chloride reduced the hyperglycemia due to adrenalin by 13 per cent. He also noted a 28 per cent smaller increase of blood sugar in rabbits which had been injected intravenously with 5 c.c. of 2 per cent potassium chloride solution, together with 3 mg. of adrenalin per kilogram of body weight subcutaneously, than with the same amount of potassium chloride. This question merits more study because the potassium in blood has been found to be higher in certain forms of diabetes. Further as to the effect of calcium on blood sugar, Cantarow, Brundage, and Housel¹² found that the intravenous injection of calcium gluconate and calcium levulinate in doses of 3.7 to 9.9 mg. of calcium ion per kilogram of body weight was followed by a decrease of 10 to 31 mg. per 100 c.c. in blood sugar within five to fifteen minutes. No inhibitory effect on insulin action was observed in the animal experiments of Fazekas and Himwich¹³ when 10 mg. of calcium chloride or 10 mg. of magnesium sulfate were added to insulin prior to injection. It is interesting to note that although calcium, magnesium, and zinc belong in the same group in the Mendeléeff table, only zinc possesses the inhibitory effect on insulin action.

Nickel-Cobalt.—Bertrand and Macheboeuf¹⁴ found the pancreas rich in nickel and cobalt. Labbe, Roubeau, and Nepveux¹⁵ confirmed the results obtained by Bertrand and Macheboeuf¹⁴ in their experiments on rabbits in which they showed that the addition to insulin of a trace of a nickel salt or of a cobalt salt intensifies and prolongs the hypoglycemic effect. Labbe, Roubeau, and Nep-

veux¹⁵ then sought to determine the action of nickel and cobalt salts on the hypoglycemic power of insulin on diabetic individuals. They conducted two series of experiments. In the first series isolated injection of nickel chloride and cobalt chloride salts in isotonic solution into diabetic individuals with malnutrition and acidosis showed that the blood sugar level is not modified by cobalt and nickel salts. Identical injections made in normal subjects showed no modification in their glycemic levels.

In the second series of experiments they sought to find whether the injection of metallic solutions would influence the hypoglycemic power of insulin on diabetic individuals in the same manner as on animals. They administered half units of insulin per kilogram of body weight to eight diabetic individuals with acidosis and malnutrition, and to one diabetic patient without malnutrition. They varied the doses of nickel and cobalt chloride injected per kilogram of body weight, the first series of patients receiving 0.1 mg. of nickel chloride; the second series, 1 mg. of nickel chloride; the third series, 1 mg. of cobalt chloride. For each patient it was possible to make two series of observations, the first with insulin alone, the second with the same quantity of insulin added to the metallic solution. For each, the two curves of glycemia with and without nickel or cobalt salts were such that no reinforcement of the action of insulin, either in intensity or duration, could be noted. They found that the injection of cobalt or nickel salts without insulin, whether in healthy or in diabetic individuals, was without hypoglycemic effect as Bertrand and Macheboeuf¹⁴ had shown to be the case with animals. They reported that action of insulin in association with nickel or cobalt salts on diabetic persons varied from that observed in healthy rabbits and dogs, a difference perhaps due to a dissimilar metabolism of the glucides in healthy animals and diabetic human beings. Magenta¹ in 1926 obtained in dogs results similar to those obtained by Blatherwick and Sahyun¹⁶ in rabbits (1927). The latter reported a slight increase of glycemia when metallic salts alone were used. Metallic salts used simultaneously with insulin exercised little if any preventive action on the hypoglycemia of dogs, and never increased the hypoglycemic effect of insulin.

Zinc.—Hove, Elvehjem, and Hart¹⁷ investigated the relationship of zinc to certain aspects of carbohydrate and protein metabolism in rats. Glucose tolerance tests were conducted by means of pipette-feeding of 0.2 Gm. of glucose per 100 Gm. of body weight after a five-hour starvation period. Tolerance curves obtained from zinc-deficient rats differed from rats on a normal diet. Liver glycogen determinations on both zinc-deficient rats and control rats revealed no difference in respect to liver glycogen. In the case of the zinc-deficient rats, these investigators found a distinct delay in the time interval necessary for the blood nitrogen to reach its maximum value. The distinct irregularity of the glucose tolerance curves obtained from zinc-deficient rats is explained as being due to a delay in the absorption rate of carbohydrate and protein from the gastrointestinal tract.

In dogs fed zinc oxide, D'Amore, Falcone, and Maramaldi¹⁸ observed occurrences of severe glycosuria. Salant and Wise¹⁹ also report glycosuria following the administration of zinc acetate and zinc malate, both orally and intravenously.

These observers explain this phenomenon on the basis of an increased permeability of the kidneys to sugar (renal diabetes).

Drinker, Thompson, and Marsh²⁰ state that glycosuria was not present in cats which had received zinc oxide in the form of a dry powder mixed with food. However, they did encounter glycosuria in two of three dogs subjected to the same method of zinc oxide administration. Curiously, gross and microscopic examination following autopsy revealed fibrous change in the pancreas of the zinc-treated cats and none in the pancreases of the zinc-treated dogs. No other organs of these animals showed pathologic change. The authors state that the amount of zinc oxide administered is greatly in excess of that usually encountered by man. Impressed by the fibrous changes in the pancreas of zinc-treated cats, and knowing through their own researches the close chemical relationship between insulin and zinc, Scott and Fisher²¹ estimated the insulin content and the zinc content of the pancreases of cats maintained on a basal diet, and also a basal diet to which zinc oxide had been added. They, too, found that the pancreas was greatly involved in the zinc-treated cats through degenerative changes in the acinar tissues. Nodular pancreatic glands with bands of fibrous tissue replacing areas of acinar tissue were observed. The islet tissue of the pancreas in both the zinc and the control groups showed no change. Amyloid deposits in the spleen and calcification in the cortex of the adrenals were noted in many of the zinc-treated cats. The liver and kidneys in both groups showed that a large amount of fat was present.

Since these changes occurred in both groups, it is not certain that zinc feeding was their specific cause. No changes were found in other tissues examined. They assert that heavy zinc feeding did not alter the total insulin content of the pancreas. Their results appear to indicate an increase in the amount of insulin per gram of pancreas, while the total insulin content remained unchanged. It was observed that on a basal diet the cat pancreas contains more zinc per gram of tissue than the liver.

The livers of zinc-fed cats contained nearly twice as much zinc per gram of tissue as the pancreases, although the cats on a basal diet contained a higher percentage of zinc per gram of tissue in the pancreas than in the liver. On the zinc diet insulin assays showed that 2.56 units of insulin were present per gram of pancreas, while on the basal diet only 1.68 units of insulin per gram of pancreas were present. The total insulin content of both groups was nearly the same (10.40 units on the zinc diet and 11.52 units on the basal diet).

Scott and Fisher²² assayed the pancreases of nondiabetic human individuals who came to autopsy and found that 1.7 units of insulin per gram of pancreas were present. In diabetic individuals who came to autopsy, they noted that the pancreas contains less than 0.4 unit of insulin per gram of pancreatic tissue. It was observed that the average zinc content of the diabetic pancreas is one-half that of the normal pancreas. The zinc per gram of pancreas in the diabetic person assays at 0.07; in the nondiabetic person, the value is 0.14. No marked differences in zinc concentration in the livers of diabetic and nondiabetic individuals were observed. It is of interest to note the marked reduction of both insulin and zinc in the pancreas of the diabetic individual. Scott and Fisher²²

suggest from this observation the possibility that a part of the zinc in the pancreas might be concerned with the storage and utilization of insulin.

Zinc Insulin Mixtures.—Zinc has been found to be present in the pancreas; it has also been found in all commercial preparations of insulin examined by Scott and Fisher.²³ Insulin solutions to which 0.02 per cent of zinc chloride are added, or equivalent amounts of zinc in the form of zinc acetate or zinc sulfate, demonstrated only 40 per cent of the original hypoglycemic activity when injected into mice. It was noted that convulsions occurred later in the group of mice that were given zinc insulin solutions than in the control group given insulin alone. This observation suggested that the action of insulin was delayed by the presence of the zinc salt. In rabbits, when the zinc insulin mixture was so adjusted that 0.24 per cent of zinc chloride was present, the action of insulin was also greatly delayed. These authors suggested that the zinc added to insulin altered the solution, so that a greatly delayed hypoglycemic action was produced. Rabbits receiving insulin alone yielded the lowest blood sugars two hours after the injection of insulin, and blood sugars reached the normal level in ten hours. Rabbits given zinc insulin showed a gradual fall in the blood sugar values during the first five hours, and blood sugar values were still below the normal level at the end of a ten-hour period. Injections of zinc sulfate solutions alone did not alter blood sugar response during an observation period of seven hours. It appears that the delayed hypoglycemic action of zinc-insulin mixtures is dependent upon some process which takes place in the solution before it is injected.

Fazekas and Himwich¹³ observed no alteration of the typical action in either dogs or cats when insulin and zinc sulfate are injected independently into separate subcutaneous areas. Injections of zinc sulfate, the same concentrations as above but without insulin, had no effect whatsoever on blood sugar levels. When 0.9 per cent zinc was used in a zinc-insulin mixture, complete inhibition of insulin action resulted.

Copper.—Ussolzew²⁴ found that intravenous injections of 0.5 mg. and 1 mg. of copper nitrate caused a lowering of blood sugar in rabbits starved for twenty-four hours previous to injection. Tkachenko²⁵ found in rabbits that the administration of 0.1 mg. of copper per kilogram of body weight caused a hypoglycemia in rabbits.

Schnetz²⁶ observed the effect of copper on carbohydrate metabolism both through studies of the isolated liver and on the intact animal. His results show that copper causes a definite lowering of the ability of adrenalin to cause mobilization of glycogen from the liver, but does not disturb the normal glycolytic mechanism. He also found that the oral administration of 20 mg. of copper sulfate per day for a period of days in normal individuals reduced both the hyperglycemia caused by the injection of 0.5 mg. of adrenalin and the hyperglycemia produced by the administration of 30 Gm. of dextrose orally. In his experiments, equivalent amount of iron salts did not influence a hyperglycemia identically induced.

Copper salts were given over a period of weeks to four persons suffering from severe diabetes mellitus. A noticeable reduction in the amount of insulin necessary to control their diabetes was observed, as was also a lowering of blood

sugar and urinary sugar and a disappearance of acetone bodies. This action of copper in reducing blood-sugar is marked in cases of high blood sugar values. When blood sugar values are within normal limits, little effect is observed. These experiments (copper-adrenalin-dextrose) on normal individuals, and those made in the course of diabetes mellitus, appear to indicate that it is to hepatic action that copper-reduction of blood sugar values is due. This hypothesis is made on the basis of the following theory: copper administered by mouth is thought to be transported by the reticulo-endothelial system to the liver. Muller²⁷ believes that copper so alters the glycogenolytic mechanism of the liver that it does not respond in its usual way to adrenalin mobilization of glycogen action, with the resulting rise in blood sugar levels. Muller²⁷ believes that copper makes for stabilization of hepatic glycogen function. Schnetz²⁶ states as a hypothesis that copper is a catalyst which helps the oxidation of carbohydrates through hepatic or extrahepatic action.

Since at present we do not know where copper is distributed in the liver nor how long it remains in it, nor what chemical unions and reactions it engages in, we can only say that it appears that the real mechanism is not yet explained. The foregoing interesting theories must remain unproved hypotheses until more data have been made available.

Aluminum Insulin Mixtures.—When 11.2 mg. of aluminum chloride were mixed with ten units of insulin before injection, Fazekas and Himwich¹³ observed no decrease in blood sugar values in the animals. When 5.6 mg. of aluminum chloride were mixed with ten units of insulin, a decrease in blood sugar values occurred, showing that the aluminum chloride at this concentration does not abolish insulin activity. Since Scott and Fisher²³ showed that potassium alum had no inhibitory effect on insulin, aluminum chloride apparently differs from potassium alum in its inhibitory effect on insulin.

Ferric Chloride Insulin Mixtures.—Maxwell and Biscoff²⁸ investigated the action of basic ferric salts in prolonging insulin hypoglycemia. Insulin was added to a dilute aqueous solution of ferric chloride which had been neutralized to the point of precipitation. In both rabbits and rats the addition of basic ferric chloride to insulin augmented the insulin action. The blood sugar of the control animals receiving insulin alone approached the normal at the fifth hour, while the blood sugar of the group that received insulin plus ferric chloride approached the normal value at the eighth hour.

Manganese.—Pignatari²⁹ noted the effect of manganese sulfate on the carbohydrate metabolism of rabbits. When 0.50 Gm. of manganese sulfate in physiologic solution per kilogram of body weight was injected daily, the animals died after the fourth or fifth injection. With doses of 0.10 Gm. of manganese sulfate, the animals remained alive for approximately one and one-half months. The first symptom of the manganese intoxication appeared after 0.80 Gm. of manganese sulfate had been administered. Pignatari²⁹ determined the fasting blood sugar level in each rabbit before the poisoning and on alternate days during the course of the intoxication. The method used for the determination of the blood sugar values was that of Bang-Condorelli.

The blood sugar values during the intoxication with manganese sulfate showed a decrease in the fasting blood sugar levels. In the final period of the

intoxication the glycemic level was so markedly decreased that in some cases the fasting blood sugar level was approximately one-half of the normal.

Pignatari²⁹ carried out glucose tolerance tests on these animals during the various stages of the intoxication with manganese sulfate. The blood sugar levels were determined until the fourth hour after the administration of the glucose. The principal characteristic of the glycemic reaction in rabbits intoxicated with manganese was the prolongation of the hyperglycemia. The hyperglycemia was due to the diminished capacity of the liver to absorb the circulating glucose and to synthesize glycogen. The hypoglycemia observed in the course of the intoxication with manganese can best be explained by a deficient and impaired glycolytic mechanism of the liver. Both the delayed hepatic glycogenesis and the deficient and impaired glycogenolysis can best be explained by changes produced by manganese sulfate on the liver.

Lead.—Von Ludwig Schmidt-Kehl³⁰ reports that rabbits fed a daily dose of 10 mg. of lead oxide per kilogram of body weight over a period of two or four months developed chronic lead poisoning. Five normal rabbits were used as controls. The administration of 2 per cent of the body weight of levulose in normal control animals, after a day of starvation, showed a rise of 16 per cent in the blood sugar values. In the five animals with chronic lead poisoning, the increase in blood sugar values rose to 35 per cent. These determinations were made according to the method of Hagedorn and Jensen. Histologic examinations revealed no pathologic changes present in either normal or leaded animals. It was concluded that in chronic lead poisoning of rabbits, even without the presence of any anatomic and histologic changes in the liver, there is already present undiscernible damage, as evidenced by increased blood sugar values in the leaded animals.

Cavagliano³¹ observed the occurrence of glycosuria in patients during episodes of lead colic. He reports that the administration of 1.5 Gm. of glucose per kilogram of body weight to patients recovering from lead colic resulted in a glycosuria that manifested itself for a period of four hours. After considering alimentary glycosuria and renal glycosuria as possible explanations for this mechanism, he concludes, "The glycosuria indicates the functional disturbance of the liver caused by lead."

It has been demonstrated that injections of lead, whether in solution or in a colloidal state, localize chiefly in those organs that are rich in reticulo-endothelial elements, and hence particularly in the liver. Colloidal lead, like mineral colloids in general, when injected, are prevalently deposited in the liver. The variations of the glycemic levels can be studied before and after the injection of these colloids.

Merlini³² injected carefully standardized colloidal lead preparations into the marginal veins of rabbits. The normal glycemic levels of rabbits were determined in the control group. The blood sugar values varied from 116 mg. to a minimum of 81 mg. of glucose per 100 c.c. of blood. The average value of the blood sugar determinations in this control group was 83.9 mg. of glucose per 100 c.c. of blood. Merlini noted that rabbits which had received 0.021 Gm. of lead per kilogram of body weight after a few hours had blood sugar values

ranging from 54 to 58 mg. of glucose per 100 c.c. of blood. When the dose of the colloidal lead solution was reduced so that 0.01094 Gm. of lead per kilogram of body weight was injected daily for a period of five days, and then fasting blood sugar levels were determined, a hypoglycemia was noted. The level of this hypoglycemia was never found to be much below 50 mg. of glucose per 100 c.c. of blood. Merlini's data show that the rabbits reacted to colloidal lead with hypoglycemic reaction according to the dose administered.

Phosphotungstic Acid—Phosphomolybdic Acid.—Mukherjee³³ in 1925 noted the effects of the phosphotungstates and phosphomolybdates on carbohydrate metabolism when taken internally. Experimentally, phospho-24-tungstic acid, phosphomolybdic acid, molybdic acid, silicotungstic acid, sodium tungstate, and ammonium phospho-18-tungstate when taken by mouth lower the glycemie level in both rabbits and diabetic human beings. The experiment using diabetic patients was as follows: Three hours after administration of insulin there was an average blood sugar drop of 125.3 mg. per 100 c.c. of blood. Three hours after intake of 0.9 Gm. of phosphotungstic acid, an average blood sugar drop of 90 mg. per 100 c.c. of blood resulted. A diuretic action of these substances was noted while demonstrating the above hypoglycemic effects. An oxidizing action is observed when 0.1 Gm. of phosphomolybdic crystals in a 5 c.c. solution of benzidine in acetic acid turns blue, and becomes deeper in color when hydrogen peroxide is added. Benzidine and phosphomolybdic acid alone give a positive reaction. The allied substances give a positive reaction when added to alkaline phenolphthalein reagent. These substances, Mukherjee believes, act like oxidizing enzymes; and the oxidizing action associated with the hypoglycemic reaction suggests that oxidation of sugar in the tissues may produce hypoglycemia.

Mercury.—Richter³⁴ observed the presence of glycosuria associated with hyperglycemia in animals after the administration of sublimate of mercury. Frank³⁵ found that the intravenous injection of 3 mg. of bichloride of mercury into rabbits was followed by a marked glycosuria without change in the glycemie level.

Hunter and Roberts,³⁶ on the other hand, claim that in addition to the widespread tubular necrosis, distinct changes interpreted as evidences of injury can be demonstrated in the glomerular basement membranes of kidneys damaged by mercuric chloride. These alterations in the basement membrane may perhaps play an important role in the renal disturbances induced by the salts of mercury. In man, in the course of corrosive sublimate intoxication, Lepine³⁷ has observed glycosuria.

Uranium.—Lepine and Boulud,³⁸ Fleckseder,³⁹ Pollak,⁴⁰ Frank,³⁵ and Luzatto,⁴¹ reported a glycosuria variable in degree produced by uranium salts. In fasting animals, it was less and appeared later than in well-fed ones. In dogs, Frank³⁵ found that glycosuria prevailed from eight to eleven days after a single injection. Whitney⁴² states that in the acute nephritis produced by uranium there is damage to the tubular epithelium of the kidneys and to the capillaries. There is generalized capillary damage resulting in decreased permeability of the walls. Reports as to sugar concentration in the blood varied from hyperglycemic to hypoglycemic levels.

Chromium.—Vernon,⁴³ first, and Kossa⁴⁴ later called attention to the production of glycosuria by chromium salts. Kossa's studies determined the amount of sugar in both the blood and the urine of animals subjected to his experiments. He found no hyperglycemia in animals poisoned with chromate. Other investigators report contradictory findings, both higher and lower than those of Kossa. Luzzatto⁴¹ administered potassium chromate to well-fed and fasting animals and observed glycosuria and albuminuria following administration.

In addition to widespread tubular necrosis, distinct changes, interpreted as evidences of injury, can be demonstrated in the glomerular basement membranes of kidneys damaged by chromium.³⁶

Tellurium.—Luzzatto⁴¹ states that tellurium salts, in particular sodium tellurate, may cause glycosuria and albuminuria in animals, sometimes reaching 1 per cent sugar concentration. Albuminuria sets in first, followed within forty-eight hours after injection by a glycosuria which may last five days. Observations made on both fasting and well-fed animals indicated no increase in glycemie levels. Kaiwa⁴⁵ demonstrated that b-dimethyltelluronium dichloride, administered subcutaneously as well as intravenously, was effective in provoking hyperglycemia. The hyperglycemia first begins to appear one-half to one hour after injection, and lasts from two to four hours. Additional experiments were made on rabbits of which the splanchnic nerves had been bilaterally sectioned in order to observe whether the hyperglycemia due to b-dimethyltelluronium dichloride is of central origin. Results were identical, showing no involvement of the central mechanism. However, experiments on bilaterally suprarenalectomized rabbits showed a lower level of hyperglycemia than that found in either the normal or the splanchnicotomized animals.

COMMENTS

It is apparent that with the exception of sodium, potassium, nickel, and cobalt, the investigations of the direct effect of metals on carbohydrate metabolism have consisted, for the most part, of animal experimentation. Routine glucose tolerance tests in clinical cases of metal intoxications will probably yield interesting and significant information in this field. The data thus obtained will aid greatly in elucidating the physiologic and pathologic relationships of the metals and carbohydrate metabolism.

SUMMARY

1. The sodium ion depresses the blood sugar level in rabbits. In juvenile diabetic patients the administration of sodium salts decreases both blood sugar level and glycosuria. The mechanism of this action is unknown.
2. Potassium salts increased the blood sugar concentration and glycosuria of juvenile diabetic persons. This effect appears to be due to a stimulating effect on adrenalin discharge and is inhibited by magnesium.
3. There is no unanimity of opinion concerning the effect of calcium on the glycemie levels of various experimental animals. Calcium salts appear to depress the hyperglycemic effect of epinephrine in animals.

4. Nickel and cobalt salts, when added to insulin, delay the effect of the latter in normal rabbits and dogs, but not in diabetic human beings. Nickel and cobalt salts, when given alone, have no effect on blood sugar level of man or animals.

5. Zinc-deficient diet delays the absorption of carbohydrate from the gastrointestinal tract of rats. Zinc oxide has been found to produce glycosuria in dogs and pancreatic fibrosis in cats. The zinc content of the pancreases of diabetic persons is greatly below normal.

6. Zinc, aluminum, ferric chloride, nickel, or cobalt, when mixed with insulin, delays the action of the latter; calcium, magnesium, and potassium alum do not delay the effect of insulin when mixed with it.

7. Lead and manganese decrease the fasting blood sugar levels.

8. Phospho-24-tungstic acid, phosphomolybdic acid, molybdic acid, silico-tungstic acid, sodium tungstate, and ammonium phospho-18-tungstate appear to cause a decrease in blood sugar of diabetic persons.

9. Glycosuria has been observed after the administration of mercury, uranium, and chromium.

10. The administration of copper salts, both in man and animals, causes a decrease in the ability of adrenalin to mobilize liver glycogen.

ALLERGY IN RELATION TO PURPURA*

J. WARRICK THOMAS, M.D., AND J. R. FORSYTHE, M.D., CLEVELAND, OHIO

SIR WILLIAM OSLER¹ in 1914 reported a series of purpura cases compiled over a period of nineteen years. He stressed the possible relationship of purpura with erythema multiforme or the erythema group, and pointed out the association of skin lesions and visceral symptoms. Alexander and Eyer-mann² in 1927 reported two patients in whom purpura was definitely related to the eating of various foods, as these patients were free from symptoms on the elimination of the incriminated food. In 1921 Duke³ reported a patient with severe abdominal pain associated with purpura and angioneurotic edema in whom there was a strong maternal and paternal familial history of purpura. Sensitization studies revealed marked reactions to a number of foods, and the purpura as well as the angioneurotic edema and abdominal complaints cleared up following a program of dietary restrictions. Peshkin and Miller,⁴ in their review of the literature, reported that purpura has been known to follow the administration of such drugs as mercury, aniline, iodine, pyridine, quinine, belladonna, ergot, acetphenetidin, salicylic acid, and arsphenamine.

Eyer-mann⁵ observed 18 cases in which purpura followed ingestion of certain foods. He stated that regardless whether the purpura and associated symptoms appear to be induced by infection, by ingestion, or by inhalation, the common factor appears to be a disorder of the capillary mechanism which leads to congestion, exudation, or hemorrhage. It may also lead to skin lesions, such as erythema multiforme, urticaria, angioneurotic edema, and purpura. In addition, he feels that exudations into the stomach or intestinal walls cause nausea, vomiting, and abdominal colic.

There are a number of other authors including Squier and Madison,⁶⁻⁸ Rowe,⁹ and Brown,¹⁰ who have contributed materially to the subject of purpura as related to allergy.

DISCUSSION OF ALLERGIC PURPURA

In a series of 64 patients with purpura hemorrhagica observed in the Cleveland Clinic, ten were thought to have a possible allergic factor related to their problem, and for this reason a complete allergy survey was done. The patients were analyzed from the viewpoint of the various purpuric manifestations, as well as for the correlation of the age incidence and sex.

There were four males and six females in the series. It was observed that the age factor did not play a prominent part, as there was an equal distribu-

*Normal averages as follows:

Coagulation time = 5 to 10 minutes.

Clot retraction = 1 to 2 hours.

Platelet count = 250,000 to 500,000.

Bleeding time = Up to 3 minutes.

a. Chronic nephritis; intestinal hemorrhage.

b. Chronic dental sepsis; acute nephritis; chronic prostatitis.

c. Essential hypertension; multiple myeloma; scurvy; ptosis of kidney.

tion of patients in the first, second, third, fourth, and seventh decades. Seven of the patients had tourniquet tests performed, and of this group five gave characteristic petechiae.

From the point of view of the different purpuric manifestations, 9 had petechiae, 7 had ecchymotic spots, 4 had recurrent attacks of epistaxis, 3 had bleeding gums, 2 had bloody stools, 2 had an abnormal catamenia, and one had had a cerebral hemorrhage.

PURPURA AND RELATED ALLERGIC MANIFESTATIONS

Table I shows the distribution of the various allergic manifestations associated with purpura hemorrhagica as related to family history, blood findings, and other associated clinical manifestations. There were only two patients who had a definite thrombopenia in addition to their allergy (see Cases 8 and 10). A detailed review of the ten cases follows:

CASE 1.—A boy, 2 years old, first visited the clinic in 1936. His mother stated that three months prior to admission, some abdominal rumbling with mucus and blood in the stools was noted. This cleared up after a week's duration, and was followed two days later by edema of the arms and legs and by purplish spots in the skin. Since that time he has had recurrent attacks of purpura with associated swelling of the legs. There had been considerable nasal congestion in addition to frequent colds. A bilateral family history of allergy was elicited. Sensitization studies were made, and the child was found to be allergic to a number of the more common foods and inhalants. His therapeutic program consisted of the avoidance of contact with inhalants and a program of dietary restriction. Three months later he was reported greatly improved without having had subsequent purpuric lesions and with a marked improvement of his nasal symptoms.

CASE 2.—A woman complained of recurrent hives for a period of five years. During the thirteen months prior to her admission, urticarial lesions had been present almost constantly. She had experienced recurrent exacerbations of the urticarial lesions following the ingestion of orange juice. Sensitization studies were made, and a program of avoidance or elimination of the reacting inhalants, foods, and molds controlled the urticarial lesions. Two years later, following a tonsillectomy, she had some bleeding from the rectum, nose, and gums, and an increased tendency to bleed easily. Tourniquet test was positive. Sensitization studies were repeated, but she did not materially improve on this program until after taking thyroid extract and Lugol's solution for a number of years.

CASE 3.—A woman, aged 32 years, was suffering from abdominal cramps, diarrhea, and mucus in the stools. She stated that certain foods, such as tomatoes, peaches, and cantaloupes, aggravated these symptoms. Further history revealed a perennial allergic rhinitis and a history of eczema. She had allergy studies at this time and was placed on a program of dietary restrictions and advised to avoid inhalants. Two weeks after returning home she developed purpuric symptoms about the right knee; these were thought to be due to some allergic factor that was not entirely controlled. The symptoms later cleared up satisfactorily.

CASE 4.—A woman, 65 years old, gave a history of recurrent purpuric spots for a period of twelve years prior to her examination. The lesions occurred mostly on the legs and thighs. There was a history of asthma which cleared up on a program of hyposensitization. She was of the opinion that nervous strain, sugars, pastries, and such foods as strawberries and tomatoes caused the purpuric spots to appear. She gave positive reactions to food, inhalant, and bacteria testing, and was placed on a restricted diet and instructed to avoid inhalants to which she reacted. When last seen, fourteen months after the institution of treatment, she reported that she had been getting along well and had had no recurrence of her purpura.

CASE 5.—A woman, aged 37 years, complained of a recurrent purpuric rash over her abdomen for the past several years. Eight weeks prior to admission she had observed this rash appearing over her arms and about her ankles. No known etiologic factors were elicited. She had had some stinging irritating lesions, presumably hives, following contact with hollyhocks, and on one occasion when changing feathers from one pillow to another. She gave a history of perennial rhinitis and frequent colds, especially during the winter months. She frequently experienced heartburn after eating white bread and pancakes. There was a definite family history of allergy. Physical examination revealed nothing of clinical significance other than the purpuric areas over her arms, thighs, and legs. Tourniquet test was positive and special blood examinations were within normal limits. She was placed on a restricted diet and told to avoid inhalants to which she reacted.

CASE 6.—A 16-year-old boy was first seen on March 3, 1939. He reported that in September, 1938, he worked in a new store for two days, a total of twenty-eight hours, during which time tar was being heated in the basement to repair the roof. The tar fumes were very strong during the entire period he was working. Within four or five days following exposure to the tar fumes, he developed severe cramps in his legs. This was followed by nausea and vomiting, and by black stools without diarrhea. Two weeks after his exposure he first developed reddish-purple spots of varying size on his arms, legs, and lower abdomen, and considerable edema of the feet. Within the next eight weeks (spent entirely in bed) the purpura was noted in successive crops. Hematuria was then discovered. On December 12, 1938, severe edema of the face became apparent, with the onset of more petechiae. On March 1, 1939, he again developed nausea and vomiting, with bloody diarrhea and hematuria, and the onset of a new crop of petechiae.

The boy had been having a chronic catarrh for many years which was worse during the winter months. He has noted definitely that being in contact with dogs and cats tended to make his nasal condition worse, and that the catarrh improved when he stayed away from them. Since September, 1938, hives have been noted at infrequent intervals. Eating of cooked cabbage, oatmeal, and several other cooked vegetables definitely caused nausea and vomiting. There was conclusive family history of allergy. The boy's paternal grandmother had chronic eczema, a paternal uncle has hay fever, and one paternal cousin has asthma. By further questioning, the fact was elicited that as a child the patient had chewed tar in large wads upon numerous occasions. Routine sensitization studies were performed which revealed very strong reactions to a number of the more common inhalants, molds and bacteria. Very strong reactions were likewise noted to a number of the more common foods and sea foods. Patch test to mild tar ointment in a lanolin base gave a slight erythema (patch test to lanolin alone was negative), while a patch test to crude tar ointment gave a very strongly positive reaction. The patient was placed on an allergy program consisting of dietary restriction, avoidance and hyposensitization with the positive inhalants to which he reacted. He was further advised to stop smoking entirely and to keep a food diary.

He was seen at weekly intervals for a period of six months and continued his program of hyposensitization during that period.

The urine examination of the patient revealed repeated specimens showing albumin varying from one to four plus, both granular and hyalin casts in varying numbers, and red and white blood cells. The entire picture showed a definite improvement, and the last several specimens showed only a trace of albumin, three to five red and white blood cells, and rare granular cast on microscopic examination.

A definite improvement in symptoms characterized by a feeling of general well-being, increased appetite, and a weight increase of 15 pounds after the first month, was observed. He continued for several weeks to have scattered purpuric lesions over the lower extremities, which gradually disappeared. He was last seen nine months after the treatment was instituted, and at that time his allergy was very well controlled. He had had no recurrence of his purpuric lesions. Urine examination, however, revealed few red blood cells. He has gained 50 pounds in weight since treatment was first started. We feel that he has a chronic nephritis.

CASE 7.—A man in his 60's gave a history of having had recurrent episodes of epistaxis, mainly during the winter months. Purpuric or ecchymotic spots were noted over the legs for a month prior to his visit to the clinic. He gave a history of recurring attacks of nasal obstruction, postnasal drip, and rhinorrhea for thirty years. The purpuric lesions were noted over the lower extremities and abdomen. He gave minimal reactions to the various allergens with the exception of bacterin, to which he gave very marked delayed reactions—more so than is usually encountered.

The patient's urine was examined at daily intervals during his period of hospitalization, which was of ten days' duration. Significant findings were albumin, varying from 1 to 3 plus. Both hyalin and granular casts were seen on microscopic examination with both red and white blood cells from zero to eight in number. There is no question of an acute nephritis in this case.

He was placed on a program of dietary restrictions and hyposensitization. He did not follow his program and we did not hear from him since outlining his treatment until recently, when his doctor reported his death due to chronic nephritis.

CASE 8.—A little girl, 2½ years old, had an atopic dermatitis showing the characteristic distribution. Dietary restriction cleared up the eczema satisfactorily without recurrence, but not the purpura. Since there had been a definite persistence of the purpuric lesions along with a thrombopenia, a splenectomy was performed. The patient is doing well with no recurrence of purpura over a three-month period, her platelet count being 90,000. Her purpura in retrospect was not related to allergy. The atopic dermatitis responded satisfactorily to treatment.

CASE 9.—A man, 30 years old, gave a history of recurrent crops of ecchymotic areas over his lower extremities for a period of five months. In addition, he stated that he had had asthma practically all his life. His only suggestion relative to the purpura was that he had been taking some white homeopathic pills which he had started about the time of the onset of symptoms. He further stated that he had had periods in which he was symptom-free, during the time that he was receiving the medicine. There was a very definite familial history of allergy. Physical examination revealed purpuric lesions over both lower extremities, with an associated scabies infection involving the trunk and groin.

There was some frank edema of the arms and legs, and his blood pressure was systolic 164 and diastolic 116 and later dropped to systolic 160 and diastolic 104. His urine showed a faint trace of albumin only on two occasions. Roentgenograms showed singular dense nodular areas in both lower lungs, and no definite etiology of this process could be determined. His eleventh and twelfth ribs revealed numerous tumor areas, and later he had pathologic fractures of these ribs. This was felt to be a possible multiple myeloma. Pyelograms were made, and the right kidney was found placed just below the rim of the pelvis. He received x-ray treatment over the ribs, and following this he showed some general improvement. Continued treatment over a period of months showed a definite improvement with a subsidence of the edema. It was very questionable as to whether his purpura was related to his allergy; however, the purpura cleared after several months.

Sensitization studies were done, and he was found allergic to a number of the common foods, inhalants, and molds. He was placed in a strict dietary regime, including the elimination of drugs, and instructed regarding the avoidance of inhalants. He was seen eighteen months after the original program of treatment was outlined and reported that he had been free of purpuric symptoms, and that he had observed a recurrence of his asthma only following the ingestion of milk.

CASE 10.—The other patient with a thrombopenia was a woman in her 20's who had definite seasonal (ragweed) hay fever and asthma, as well as urticaria and perennial rhinitis. She was placed on a program of pollen and inhalant hyposensitization. Her history revealed purpuric lesions for twelve years. She had an exacerbation of her purpuric symptoms following strenuous exercise, and on one occasion had a transient hemiplegia for several days. She did not follow recommendations regarding therapy, and her allergy symptoms have continued. Purpuric symptoms persisted with a low platelet count, and a splenectomy was advised. The splenectomy was performed and since then there has been no recurrence of purpura.

COMMENTS

The question of allergy has to be ruled out as an etiologic factor in purpura hemorrhagica. When a patient presents a frank allergy at the time of the purpuric lesions, such an allergy should be investigated and controlled if possible. When patients fail to respond to general therapeutic measures, even though there is no history of allergy, an allergy investigation is warranted, as well as in the case presenting only a family history of allergy.

Our study brings out very conclusively that an inhalant factor should be considered as a possible cause in some cases, and that when such a factor has been controlled the patient may respond to treatment as shown in Case 6.

It has been definitely proved that a program of dietary restrictions alone will control certain cases (Case 4).

SUMMARY AND CONCLUSIONS

1. Allergic manifestations, a personal history of allergy, or a family history of allergy warrants an allergy investigation as a possible etiologic factor in purpura hemorrhagica.

2. When all other methods of treatment have proved unsuccessful, an allergy investigation is warranted as a possible etiologic factor.

3. Of 64 patients with purpura hemorrhagica ten had complete allergy surveys as a possible allergic etiologic factor. Of these ten a positive family history of allergy was elicited from eight.

4. Thrombopenia was observed in two of the ten patients presenting a definite allergic problem.

5. One or more allergic manifestations were found to be present in each of the ten patients studied.

6. Petechiae were observed in nine patients and ecchymotic areas were observed in seven. These were the most frequent purpuric lesions demonstrated.

7. Two patients presented frank and common allergic manifestations but failed to show any improvement in their purpuric symptoms until after splenectomy. In both of these cases the platelet count was definitely reduced.

8. Chronic nephritis was present in two patients studied.

EFFECT OF SULFAPYRIDINE ON STAPHYLOCOCCUS TOXIN*

AN IN VIVO STUDY IN THE RABBIT

R. H. RIGDON, M.D., ANNE HAYNES, B.S., AND ALYS LIPSCOMB, A.B.
MEMPHIS, TENN.

CARPENTER and Barbour¹ observed that staphylococcus toxin was inactivated in vitro by sulfanilamide. They found that 92 per cent of 630 mice survived when injected intra-abdominally with a sulfanilamide-staphylococcus toxin mixture. All 195 controls died when given toxin alone. These investigators also noted that the in vivo action of staphylococcus toxin was less marked when sulfanilamide was given either before or subsequent to the toxin. Carpenter, Barbour, and Hawley² likewise found that 89 per cent of 400 mice injected intraperitoneally with a sulfanilamide-staphylococcus toxin mixture survived while all of a group of 100 controls that received only the toxin died.

Rigdon and Freeman³ observed that sulfapyridine had no effect on the hemolytic, the skin necrotizing, and the lethal factors in staphylococcus toxin. They did note, however, a bacteriostatic action produced by this drug on staphylococci in vitro and also a variation in the degree of the action of sulfapyridine on three different strains of staphylococci.

The effect of sulfapyridine on the lethal action of staphylococcus toxin is studied in the present experiment.

MATERIALS AND METHODS

Fifteen cubic centimeters of a 25 per cent solution of sulfapyridine† in a 50 per cent dextrose solution were injected into the marginal ear veins of 28 normal adult rabbits. A similar quantity of 50 per cent dextrose was given to 18 animals. Five-tenths gram of sodium sulfapyridine in 5.0 c.c. of saline was injected intravenously into each of five rabbits. Thirty minutes following the injection of the sulfapyridine each rabbit was given either 0.15 c.c. or 0.3 c.c. of staphylococcus toxin intravenously. For one of the control observations 34 rabbits were given a corresponding amount of staphylococcus toxin. For a second control 10 rabbits were given 2,800 units of staphylococcus antitoxin intravenously and thirty minutes later 0.3 c.c. of staphylococcus toxin. The time of death was recorded. Animals surviving for forty-eight hours or longer were considered protected against the lethal effects of this toxin.

*From the Department of Pathology and Chemistry Laboratory, Division of Medicine, University of Tennessee, Memphis.

†Aided by grants from the Council on Pharmacy, American Medical Association; John and Mary R. Markle Foundation and a special grant from the University of Tennessee.

Received for publication, March 22, 1940.

†The sulfapyridine in dextrose and the staphylococcus toxin and antitoxin were supplied by Lederle Laboratories. Merck & Co. supplied the sodium sulfapyridine.

The amount of free sulfapyridine in the blood was determined by the method of Marshall and Litchfield.⁴ Blood was removed from the heart at the following intervals: thirty minutes, and one, two, three, five, and eight hours. Groups of four rabbits were bled at alternate intervals. The average sulfapyridine determination was used to establish the points on the curve (Chart 1).

TABLE I
EFFECT OF SULFAPYRIDINE ON LETHAL ACTION OF STAPHYLOCOCCUS TOXIN
(All injections were made intravenously.)

NUMBER OF RABBITS	SULFAPYRIDINE	AMOUNT OF STAPHYLOCOCCUS TOXIN (C.C.)	AVERAGE WT. (GM.)	NO. AND TIME* OF DEATH FOLLOWING INJECTION OF TOXIN
24		0.3	2,030	Group A 19 Group B 2 Group C 1 Survived 2
20	15 c.c. of 25% sulfapyridine in 50% dextrose	0.3	2,578	Group A 14 Group B 5 Group C 0 Survived 1
13	15 c.c. of 50% dextrose	0.3	2,493	Group A 3 Group B 4 Group C 1 Survived 5
10		0.15	1,334	Group A 3 Group B 3 Group C 2 Survived 2
8	15 c.c. of 25% sulfapyridine in 50% dextrose	0.15	1,315	Group A 0 Group B 3 Group C 4 Survived 1
5	15 c.c. of 50% dextrose	0.15	1,558	Group A 1 Group B 2 Group C 1 Survived 1
5	0.5 Gm. of sodium sulfapyridine in 5 c.c. of saline	0.15	1,390	Group A 1 Group B 4 Group C 0 Survived 0
10	2,800 units of staphylococcus antitoxin	0.3	1,870	Group A 0 Group B 0 Group C 0 Survived 10

*Group A—Rabbits dying from 0-2 hours following injection of the toxin.
Group B—Rabbits dying from 2-12 hours following injection of the toxin.
Group C—Rabbits dying from 12-48 hours following injection of the toxin.

EXPERIMENTAL

The number of rabbits used in each group, the amount of sulfapyridine in dextrose, dextrose alone, sodium sulfapyridine in saline, staphylococcus antitoxin, and staphylococcus toxin, and the number of rabbits that died at the different intervals are shown in Table I. It is evident from these data that neither sulfapyridine in dextrose nor sodium sulfapyridine in saline prevents death produced by an intravenous injection of staphylococcus toxin. A total of 2,800 units of staphylococcus antitoxin, given thirty minutes before the lethal dose of toxin, completely protects rabbits against the toxin.

Chart 1 shows the concentration of free sulfapyridine in the blood after an injection of sulfapyridine in dextrose. The rate of excretion appears to be very rapid. The free sulfapyridine in the blood at specific intervals after an intravenous injection of 0.5 Gm. of sodium sulfapyridine in saline is as follows: thirty minutes, 13.2 mg. per cent; one hour, 13.3 mg.; two hours, 9.2 mg.; three hours, 4.46 mg.; and five hours, 2.4 mg.

Chart 1.—Amount of free sulfapyridine in the blood of rabbits following an intravenous injection of 15 c.c. of a 25 per cent solution of sulfapyridine in 50 per cent dextrose.

It is interesting to observe in Table I that rabbits given 15 c.c. of a 50 per cent solution of dextrose and 0.3 c.c. of staphylococcus toxin thirty minutes later, live for a longer time than those animals given either the sulfapyridine in a similar quantity of dextrose and 0.3 c.c. of staphylococcus toxin or the toxin only. The rabbits given both the sulfapyridine in dextrose and only the dextrose bled very freely from the venous puncture following each injection. There was no difference in either the bleeding or the clotting time of these rabbits when compared with the controls.

Two rabbits died while they were being injected with the sulfapyridine in dextrose. One died while receiving the dextrose. The ear in which both the sulfapyridine in dextrose and the dextrose were injected became edematous after several minutes. Extensive necrosis of the ears usually occurred in those rabbits that survived the lethal action of the toxin.

DISCUSSION

The data presented here show that sulfapyridine has no inhibitory effect on the lethal action of staphylococcus toxin when given intravenously to the rabbit. Taylor and his associates⁸ are of the opinion that when sulfapyridine is given in dextrose to man the drug circulates in the blood in a form different from other sulfapyridine preparations. If such occurs in the rabbit, one would then conclude from these experiments that it also has no effect on the lethal action of staphylococcus toxin.

There is a significant difference in the twelve-hour survival rate of the rabbits given dextrose and 0.3 c.c. of staphylococcus toxin over those injected with only the toxin. This difference is two and one-half times its standard error. A larger number of rabbits given dextrose and 0.3 c.c. of staphylococcus toxin lived more than two hours longer than those animals injected with sulfapyridine in dextrose and a similar quantity of toxin. There is no difference in the low hour survival rate, however, in the rabbits given sulfapyridine in dextrose and toxin over those animals given only the staphylococcus toxin.

The failure of the rabbits that received the sulfapyridine in dextrose to survive for a longer time than the rabbits given only the toxin suggests that the effect of the sulfapyridine, plus that of the toxin, is sufficient to produce death more quickly than the toxin alone. A phenomenon similar to this was observed by one of us (R. H. R.) in mice given sulfapyridine and staphylococcus toxin. Eighteen mice in a group of 30 died when a mixture of sulfapyridine and toxin was given intraperitoneally, while only 15 died in a group of 30 when given only the staphylococcus toxin.

The results of this experiment suggest that the hypertonic dextrose solutions may inhibit the union of staphylococcus toxin with tissue cells. One of us (R. H. R.) recently studied hemolysis produced by staphylococcus toxin on rabbit red blood cells suspended in hypertonic solution of sodium chloride and found an inhibition in the rate and the degrees of lysis which paralleled the concentration of the salt.⁹ In another study it was observed that necrosis failed to occur at the site of intradermal injection of staphylococcus toxin when a 5 per cent solution of sodium chloride was previously injected into the local area of the rabbits' skin. Necrosis occurred in these rabbits below the point of injection of the toxin. It was thought that "the inhibitory action of sodium chloride on the dermal necrosis produced by staphylococcus may be the result of the action of the salt on the tissue cells. The change effected may inhibit the union of the toxin with the cells. This union apparently is responsible for the necrosis."

Smith⁷ has observed that sucrose, glucose, glycerol, and ethylene glycol inhibit the necrotic action of staphylococcus toxin. This inhibition appears to be related to the hydroxyl content rather than to the molecular weight. The mechanism of the action is one of partial destruction of the toxin. The staphylococcus toxin in our experiment must not have been destroyed, since the total number of deaths within a period of forty-eight hours in the group of rabbits receiving the dextrose and the toxin and the group receiving only the toxin show no significant difference.

It appears that the rate of excretion of sulfapyridine in dextrose following an intravenous injection in the rabbit is similar to that which occurs in man.⁸

The results of this experiment suggest that sulfapyridine would have no effect on the toxin liberated by certain strains of staphylococci in vivo. The pathologic lesions caused by toxin-producing strains of staphylococci in vivo are similar to those lesions produced by staphylococcus toxin which was prepared in vitro and then injected locally into experimental animal.^{9, 10} Any effect that sulfapyridine might have on a staphylococcus infection apparently would be other than by its action on the toxin.

CONCLUSIONS

Sulfapyridine does not inhibit the lethal action of staphylococcus toxin in the rabbit.

Rabbits given an intravenous injection of 50 per cent dextrose and thirty minutes later staphylococcus toxin survive for a longer time than those animals given only staphylococcus toxin.

ELECTROCARDIOGRAPHIC CHANGES FOLLOWING THE INTRAVENOUS ADMINISTRATION OF MAGNESIUM SULFATE*

III. COMBINED EFFECT WITH DIGITALIS

J. ROSCOE MILLER, M.S., M.D., AND T. R. VAN DELLEN, M.S., M.D.
CHICAGO, ILL.

IT HAS been previously shown by means of the electrocardiogram that magnesium when given intravenously has a definite effect on the cardiac conductive system.¹ This effect consists of an early acceleration followed by slowing, with delay in the atrioventricular and intraventricular conduction time and increased excursion of all complexes. It has been shown that this action of magnesium upon the conductive system is not central but direct.²

Zwilling^{3, 4} showed that magnesium had a beneficial but temporary effect on digitalis intoxication. He found it useful in combating ectopic impulses from any source, paroxysmal tachycardia, ventricular fibrillation and heart block. He believed that magnesium had no untoward effect on an already damaged conduction system. He was able to save rabbits who had been given lethal doses of digitalis with repeated small doses of magnesium. All control animals died. Similar studies were done on frogs. Block and Pick⁵ confirmed the clinical studies of Zwilling, citing a single case. Smith, Winkler, and Hoff⁶ concluded from their studies on magnesium that Zwilling's work has little physiologic support since such arrhythmias develop spontaneously or can be evoked in the presence of a greatly increased concentration of magnesium in the serum.

The present problem was undertaken to ascertain the effect of magnesium sulfate, as measured by the electrocardiogram, on the conductive system of the digitalized dog.

METHOD

As in previous experiments^{1, 2} the unanesthetized dog was placed on the left side and electrodes were attached to the right front and left rear legs, thus corresponding to the conventional second lead. Electrocardiograms were made on a string galvanometer type machine. Both magnesium sulfate and digitalis were injected into the right saphenous vein.

EXPERIMENTS

Each dog underwent three separate experiments at no less than weekly intervals. These consisted of (1) the administration of magnesium sulfate, (2) digitalis, and (3) digitalis followed in twenty minutes by magnesium.

*From the Department of Medicine, Northwestern University Medical School, Chicago.
Received for publication, March 29, 1940.

Experiment 1.—Magnesium was administered intravenously, and the results obtained were in agreement with those previously reported.

Dog 1, weight 13.6 kg., received 10 c.c. of a 20 per cent magnesium sulfate solution given at the rate of 2 c.c. per minute (Fig. 1). The rate was at first accelerated following by slowing. The P-R interval increased from 0.16 to 0.18 second, and the QRS interval from 0.04 to 0.06 second. The T-waves originally inverted became diphasic.

Fig. 1.—Dog 1. A, Normal graph. B, Following the injection of magnesium sulfate. Note increase in rate (130). C, Twenty minutes after injection.

Dog 2, weight 20.5 kg., received the same amount of magnesium sulfate. The changes in rate were not unlike those of Dog 1. The P-R interval increased from 0.14 to 0.18 second, and the QRS interval from 0.05 to 0.07 second.

Experiment 2.—In this experiment digitalis (Digalen) was given intravenously as rapidly as possible. It was found that approximately $1\frac{1}{3}$ eat units per kilogram of body weight were sufficient to produce definite electrocardiographic changes. These changes consisted of bradycardia, slowing of the auriculoventricular and ventricular conduction times, and increased excursion of the T-wave. The only objective evidence of toxicity was vomiting, although as much as 28 eat units were given intravenously.

Dog 1 received 20 eat units of digitalis (Digalen). The rate fell from 80 to 60 beats per minute (Fig. 2). The P-R and QRS intervals increased from

Fig. 2.—Dog 1. *A*, Normal graph. *B*, Twenty minutes after the intravenous administration of 20 cat units of digitalis (Digalen). Note the bradycardia, increased P-R interval, and elevation of the T-wave.

Fig. 3.—Dog 1. *A*, Normal graph. *B*, Twenty minutes after injection of 20 cat units digitalis (Digalen). *C*, Following injection of magnesium sulfate solution. *D*, Twenty minutes later. P-R interval now 0.20 second. *E*, Eighteen hours from beginning of experiment.

0.11 to 0.13 second and 0.04 to 0.05 second, respectively. The T-wave became more upright by 100 per cent. These changes were still present at the end of twenty-five minutes, at which time the experiment was terminated.

Dog 2 received 28 cat units of digitalis. The P-R interval increased from 0.16 to 0.18 second, but the QRS complexes were unaffected. The T-wave became more sharply inverted. A marked sinus arrhythmia occurred.

Experiment 3.—The same amount of digitalis was then given to each animal as in previous experiments, followed in twenty minutes by the same amount of magnesium sulfate. Following the administration of digitalis, tracings similar to those in Experiment 2 were obtained.

After the administration of magnesium the rate in Dog 1 increased from 40 to 100 beats per minute, following which it became slower, but at no time did it approach the bradycardia attained with magnesium only (Fig. 3). The P-R interval, which had been 0.12 second at the beginning of the experiment, increased to 0.14 second following administration of digitalis, and to 0.20 second following magnesium. The latter auriculoventricular conduction time is far in excess to that obtained in Experiments 1 and 2. A marked sinus arrhythmia which had developed following the administration of digitalis almost disappeared following the administration of magnesium; however, numerous premature ventricular contractions were now present. An electrocardiogram made eighteen hours later was not unlike that seen at the beginning of the experiment, except for a slight prolongation of the P-R interval most likely of digitalis origin.

When magnesium was administered to Dog 2, the P-R interval, which was originally 0.16 second and had been elevated to 0.18 by digitalis, was increased to 0.28 second. Instead of the sinus arrhythmia which followed the administration of digitalis, a 2:1 heart block developed.

In Dog 3 magnesium not only failed to control a 2:1 heart block produced by digitalis, but also prolonged the auriculoventricular conduction time from 0.16 to 0.22 second, and the ventricular conduction time from 0.06 to 0.07 second. In Dog 4 digitalis produced an occasional 2:1 heart block, but following the administration of magnesium a continuous block developed. The T-waves became sharply inverted, and the auriculoventricular conduction time increased from 0.20 to 0.22 second.

These results do not agree with the clinical reports of Zwillinger. Magnesium sulfate given to the digitalized dog failed to regulate the sinus arrhythmia and actually provoked the occurrence of premature beats and heart block. Magnesium sulfate is also capable of prolonging the auricular conduction time in excess of that resulting from digitalis or magnesium alone. An initial increase in rate was noted, followed by slowing, but the rate was more rapid than that produced by digitalis. This apparently demonstrates that magnesium overcomes the vagal stimulation of digitalis.

CONCLUSIONS

1. In the digitalized dog magnesium sulfate is capable of altering the contour of the T-waves and producing a further delay in auriculoventricular conduction time in excess of that of digitalis or magnesium alone.

2. In the digitalized dog magnesium sulfate causes a brief increase in rate, followed by a slowing which approaches that obtained by digitalis. It is thus capable of overcoming the vagal stimulation produced by digitalis but for short periods only.

3. In the digitalized dog magnesium sulfate is capable of producing impulses of ectopic origin.

4. The results indicate that magnesium sulfate does not overcome the effects of digitalis intoxication but increases the degree of block and the occurrence of ectopic impulses.

COMBINATIONS OF LEAD, ARSENIC, AND OTHER CHEMICALS WITH EXPERIMENTAL ASPHYXIA OF TUMORS

FREDERICK M. ALLEN, M.D., NEW YORK, N. Y.

OTHER papers¹ have described the effects of prolonged local asphyxia of normal parts and also of tumors, especially the transplantable carcinomas and sarcomas of rats and mice. The most striking effects on tumors are (a) dark hemorrhagic congestion of the tumor in contrast to the bright arterial hyperemia of the normal tissues of the limb after ligation, and (b) extensive necrosis of the tumors, sometimes to the point of complete cure, without permanent damage to the normal tissues. Subsequent papers² will describe similar powerful effects of temporary asphyxia on spontaneous tumors, including the complete cure of one patient with cancer of the skin. While the ligation method is necessarily unsuited for any extensive use in practical tumor treatment, there is experimental evidence² of its ability to augment the effect of x-ray treatment. Other attempted combinations have been less promising, but even the negative results appear worth recording for the sake of theoretical information on the tumor problem.

Chemotherapy might be advanced by the finding of a substance which would show at least a partial selectivity for tumor tissue, and which by acting as an adjuvant to asphyxia would make the destruction of tumors safer and more

efficient. According to the theory of Neuberg and Caspari,³ the hyperemia following ligation should strengthen the chemotherapeutic action by carrying systemically injected substances in larger proportion to the tumor area and in smaller proportion to other parts of the body. For locally injected drugs there is the advantage of lying for several hours in direct contact with the tumor, with diffusion perhaps aided by altered permeability and asphyxial injury of the tumor cells.

ARSENIC

Arsenic in topical applications has been used to cure some tumors since the time of the Egyptians⁴; it is also capable of producing tumors.^{5, 6} Its pharmacology is of particular interest in the present connection. Cushman⁷ states that "arsenic is a capillary poison, dilating capillaries and permitting edema formation more readily than the normal. Arsenites and arsenious acid do not coagulate proteins or change them in any way. . . . It seems to act only upon living cells, and unlike acids and alkalis, forms no combination with the dead tissues."

Sollmann⁸ says, "Arsenical compounds act locally as mild and slow corrosives, and have been employed in superficial cancer. Systemically, they relax the capillaries and increase their permeability, thus stimulating inflammation." Arsenic is said to be toxic to all animals with a central nervous system, and to some lower forms, but it cannot be classed as a general protoplasmic poison. It has little effect on ferments, although "it is now generally believed that the arsenicals hinder protoplasmic oxidation in an unknown way." Arsenic is described as causing peripheral vasodilatation and paralysis of capillaries. "This view is favored by the fact that they have become more permeable. Intravenous injections of large quantities of salt solution will cause edema in animals poisoned with arsenic, but not in the normal. Since increased permeability of the capillaries is one of the essential features of inflammation, the phenomena of arsenic poisoning are similar to those produced by an irritating inflammation, although the primal cause is different. Arsenic produces nephritis, at first mainly vascular, but always with more or less inflammation of the epithelium." These statements, are supported by references to the well-known works of Magnus, MacNider, and others.

Sollmann further states: "Arsenicals are not precipitant and therefore irritate only weakly, even on wounds and mucous membranes, but the cells die slowly after prolonged contact. They are sometimes used for killing dental nerves, and as salves for superficial epitheliomas. Arsenic is much more destructive to pathologic cells, so that the cancerous tissue may be killed without injury to the surrounding normal tissue. As with all cancer salves, some of the deeper tumor cells usually escape, leading to inoperable recurrences."

Because the effects of arsenic so closely resemble those of asphyxia, arsenic was selected for a long series of systemic and constitutional treatments of rat tumors. Beginning with the pharmacopeial Fowler's solution, containing 1 per cent arsenic trioxide, decimal dilutions were made with physiologic saline to contain from 1 mg. to 0.00001 mg. per cubic centimeter.

Systemic Treatment.—Willberg's⁹ scale of arsenic tolerance of different species omits the rat. Experience has indicated that the lethal dose is near 1 mg.

per 100 Gm. of weight, with slight variations according to age, obesity, etc., but much more according to general strength. As weak animals have a decidedly reduced arsenic tolerance, animals with large tumors or with ligation treatment demand smaller doses than the normal. Those in best condition could receive as high as 0.9 mg. per 100 Gm., but the usual doses were smaller. Acute death from arsenic has nothing to do with organic lesions in the liver, kidneys, or elsewhere. In harmony with the above-mentioned pharmacologic action of arsenic, the picture resembles shock, and acute arsenic poisoning is perhaps correctly classified under shock. At least in the rat, the elimination is evidently rapid and the danger of cumulative effects is slight. Thus, even tumor-bearing rats were able to receive doses of 0.6 or 0.7 mg. twice or sometimes three times in twenty-four hours and to continue this sometimes more than two weeks without serious symptoms. Feeding the drug was not attempted. Subcutaneous injections produce slow ulcerations. Therefore intraperitoneal injections were usually employed.

The tumor experiments may be summarized as follows: Positive results were obtainable with single arsenic injections followed by single ligations, inasmuch as sloughing of all visible tumor tissue followed ligations of only two or three hours, which is never possible with ligation alone. Similar effects were obtained with various combinations of repeated arsenic injections and repeated ligations. A few cures were positive, in the sense of indefinite survival without tumor recurrence. But with all kinds of combinations having any decisive effect upon the tumors, the mortality was overwhelmingly high, as has been the usual rule with all chemotherapeutic attempts in the literature. Inasmuch as a lower mortality and a higher proportion of cures were obtainable with ligation alone, the combination with systemic arsenic administration did not appear promising.

Similar experiments with single and repeated arsenic injections were performed with the chicken sarcoma. Willberg⁹ gives the tolerance dose of arsenic for chickens as 0.06 Gm. per kilogram. The single doses in tumor-bearing chickens ranged only from 5 to 7 mg., but these were sometimes continued for as long as nine days. Results were positive only to the extent that sloughing of tumors after a given duration of ligation was more extensive with the arsenic injections than without. The general results were inferior to those in rats, and no cures were obtained.

Local Arsenic Injections.—Although arsenic produces remarkably little irritation in the normal tissues, it may, as already mentioned, give rise to ulcers when injected subcutaneously. As should naturally be expected, the necrotizing effect is increased by asphyxia. An approximate scale of tolerance was worked out in normal rats for combinations of one to five hours of asphyxia with arsenic dilutions from 10 mg. to 0.0001 mg. per cubic centimeter; for example, the undiluted Fowler's solution (10 mg. per cubic centimeter) caused ulceration with one hour of ligation and fatal gangrene with two hours. The concentration of 1 mg. per cubic centimeter was compatible with ligation to the limit of three hours, but caused gangrene with four hours. The solution of 0.1 mg. per cubic centimeter and weaker dilutions could be tolerated with ligations of four and

five hours. A modifying factor was later encountered, in that the quantity or location of the injection may create an increased pressure in the tissues, which, if continued, increases the tendency to gangrene.

The results with tumors may be summarized as follows: Without ligation, rat tumors are not destroyed by single local arsenic injections in any of the concentrations mentioned, or by fractional quantities infiltrated every fifteen minutes as as to keep the tumor thoroughly bathed in the solution for three or four hours, even if epinephrine or ephedrine is added. With any length of ligation, an arsenic dilution of 0.00001 mg. per cubic centimeter resembles plain saline solution in showing no perceptible effect, but all stronger solutions had an influence in destroying tumors. Cures of sarcoma 39 were obtained with ligations of two to three hours preceded by injections ranging from 0.2 c.c. of 10 mg. arsenic per cubic centimeter to 5 c.c. of 0.0001 mg. per cubic centimeter solution. In successful cases the arsenic not only shortened the time of ligation but also sharpened the specificity; the tumors were killed with less damage to the normal tissues than from ligation alone, and the resulting ulcers healed much more rapidly. Statistics are meaningless because success appeared to be governed entirely by one mechanical condition. The rat tumors are firmer in consistency than the surrounding normal tissues, so that a satisfactory infiltration of the tumor is difficult to obtain and the fluid tends to accumulate particularly in the loose subcutaneous tissue. If pressure is used to compel penetration, the normal tissues become subject to gangrene. If the first treatment is only partially successful, a repetition is practically impossible, because the injection fluid cannot be retained in an open ulcerating tumor, though collodion coating and other devices were used in the attempt. For this reason, the permanent cures, though individually rather spectacular, were comparatively few among the sarcomas and were absent with the Flexner-Jobling carcinoma and the Walker tumor.

For the same mechanical reason, attempts to combine ligation and arsenic injection in the treatment of spleen, kidney, and other intra-abdominal tumors all failed. On the other hand, a small series of serotal and testicular sarcomas turned out favorably. The testis offers a special condition because of its firm tunics, and the strong reaction of the serotum to irritation (as mentioned previously under ligation alone)¹ perhaps conduced to the cures which were obtained, with ligations of thirty to ninety minutes preceded by injection of 0.5 to 1 c.c. solution of 0.01 to 0.1 mg. arsenic per cubic centimeter. In all these cases, however, the testes became atrophied and the animals were sterile in breeding tests. Therefore, a cure with selective preservation of the testis was not obtained.

A small series of mice, with sarcoma 180 of 0.8 cm. diameter in the legs, were treated by injection of the tumors with 0.5 c.c. solution containing 0.001 mg. arsenic per cubic centimeter, followed by ligation for twenty, forty, sixty, eighty, and one hundred minutes, respectively. The tumors ligated for twenty and forty minutes merely ulcerated; the others were permanently cured. A single trial of forty minutes' ligation preceded by infiltration with 0.5 c.c. of a stronger arsenic solution (0.01 mg. per cubic centimeter) resulted in a cure.

Arsenic injections combined with ligation of the chicken sarcoma contributed to the breakdown of the tumor tissue but in no case led to a cure.

LEAD

The phenomena described by Bell¹⁰ and others, of swelling, hyperemia, and more or less necrosis in tumors under lead treatment are suggestively similar to the results of ligation. Although it is the consensus of later work that clinical cures are not thus obtained, the use of local asphyxia to reinforce the systemic lead administration appeared attractive. Thanks are due to Dr. William H. Kraemer for supplying his preparations of colloidal lead phosphate on two occasions, the first time with a small admixture of manganese, and the second time plain.

A series of 39 rats, with medium or large tumors, were not able to tolerate as high dosage as described by Kraemer.¹¹ The stronger animals, of 150 to 200 Gm. weight, often died from intravenous injections above 1.5 c.c. of the suspension, containing 4 mg. of metallic lead per cubic centimeter. For all animals it was found safest to divide doses of 1 c.c. or more into two equal injections, morning and evening. Even with these precautions, administration at the rate of about 2 mg. of lead per 100 Gm. weight daily was never tolerated for more than two or three days, and rats commonly died within a few days after the last injection. The explanation may lie in the relation between the general strength and resistance to lead. The tumor rats may have had some impairment of vigor even when they appeared in good condition, and when they were perceptibly weak or anemic their tolerance of lead was much lower.

The tumors were not perceptibly affected by small doses of lead within the limits of safety. With dangerously large or fatal doses the sarcoma and carcinoma (but not the Walker tumor) sometimes showed softening and more or less necrosis, but there was no instance of cure with survival.

When the tumor-bearing legs were ligated for periods of one to three hours in connection with the lead treatment, there were indications of an increase of necrosis in the tumors without increase of damage to the normal leg tissues. In cases where the rats survived, this necrosis appeared so complete as to give promise of cure. The purpose had been to achieve a cumulative effect of the lead and ligation upon the tumors. The dominant result was actually a cumulative effect upon the animals, the ligated ones dying from doses which could be tolerated by nonligated controls. No cures were obtained.

A few attempts were also made to combine the lead treatment with intraperitoneal or intravenous arsenic injections, given during a different time in the same day, in the hope that a nontoxic dose of arsenic might have an adjuvant action with a nontoxic dose of lead to destroy a tumor. The same sort of failure resulted, because one poison lowered the tolerance of the animal to the other.

Remarks in the literature, attributing the deaths of lead-treated rats to anemia, are erroneous. Numerous additional experiments were performed, in which single or repeated transfusions were given before or after the lead treatment, or the lead suspension was mixed with fresh heparinized rat blood for injection. It is a simple matter by these means to overcome anemia entirely even in animals which were weak or anemic before the treatment, but there is no particular alteration in the mortality.

It is fair to note that the action of a given substance is not always the same toward different tumors and in different species. Therefore, if the claims of partial tumor changes can be verified with nonfatal doses of lead in clinical cases, there may still be a possibility of its use as an adjuvant to other methods of treatment.

OTHER COLLOIDS

On account of the statements of authors, such as Nenberg and Caspari,³ concerning the tumor-killing action of various metals, and also the emphasis placed by other writers upon the special advantages of the colloid state, much time and many animals were devoted to an investigation of intravenously injected substances other than lead. Particular attention was paid to colloidal arsenic, partly because of the reports of Hendrick and Burton.¹² The other colloidal solutions included gold,¹³ silver, iron,^{14, 15} manganese, copper, antimony, sulfur, and selenium.¹⁶ Attempts were made by combinations and alternations of these to obtain a cumulative action upon the tumors, at the same time avoiding the toxicity of the individual elements, but failure resulted because the general toxic action was cumulative. In particular, it was hoped that an advantageous combination with ligation might be found by injecting immediately before ligating so that the circulating material would be held in the tumor for several hours, or by injecting immediately after release of the tourniquet so that the reactive hyperemia would flood the tumor with a maximum amount of the material. In either instance it was hoped that the asphyxiated tumor might be sensitized to the poison. All results were negative, without a single cure. Such cures as might have been expected from ligation alone were prevented by the fact that the intoxicated animals could not survive the usual duration of ligation.

DYES

Dyes have been among the most favored chemotherapeutic agents in attempts to influence cell respiration or anchor toxic substances to the tumor.¹⁴ It has been customary to search for semidiffusible substances, which would pass from the blood into the tumor and remain there for a sufficient period of time. The special conditions of ligation, already mentioned, place a premium upon the freest possible diffusibility and provide favorable opportunities for any selective action.

No experiments were performed with systemically injected dyes. A few trials were made with single or repeated local injections of dilute aqueous solutions of eosin, methylene blue,¹⁷ or gentian violet, during ligation of different rat tumors, mouse sarcoma 180, and chicken sarcoma. No cures and no improvement in results were obtained. Irregularities in distribution of the dyes were plainly visible. Addition of eosin or methylene blue to the usual arsenic solutions gave no improvement of results as compared with arsenic alone. These dyes may have been poorly chosen for diffusibility or other qualities, and the results may perhaps be improved under better technical conditions.

OTHER AGENTS AFFECTING RESPIRATION

Attempts to attack the tumor cell through its respiration have been too numerous to review.^{14, 18} The earliest stage of this research in the Physiatrie Institute included keeping the animals in glass chambers under various reduc-

tions or increases of oxygen pressure. Later some trials were made with chemical agents, such as potassium cyanide, to depress respiration, and with dinitrophenol to increase cell metabolism.¹⁹ Oxygen enrichment was also undertaken by subcutaneous and intraperitoneal injections of oxygen several times in each of the twenty-four hours, which sufficed to maintain an abnormally bright color of the venous blood. Chronic carbon monoxide poisoning was established by this same injection method, using ordinary illuminating gas. Preliminary tests determined the minimum lethal doses of these injections for normal animals, which could thus be kept saturated to such a point that the blood remained cherry red and death resulted from a slight increase of the injections. The only new principle involved was the systemic injection of the above agents in connection with local ligation, as well as local injections of the solutions and gases directly into the region of the ligated tumor. Although these experiments in the aggregate represented much work, the results were so completely negative as to require no detailed description.

STREPTOCOCCUS TOXIN

A few intravenous injections of Coley fluid²⁰ were tried, together with a larger number of local infiltrations with this fluid, or living or killed streptococcus cultures. Special attention was given to repeated infiltrations, and particularly to various combinations with ligation. The tissue reaction in the rat is different from that in man, so that the indurated swellings which are familiar clinically¹⁸ are not obtainable in the rat. Neither a curative tendency nor the slightest indication of a selective toxicity of the streptococcus products for tumor as compared with normal tissues was found.

Streptococcus toxin can best be classified along with arsenic in its action upon the blood vessels. The principal error in dealing with such remedies has consisted in the search for a specific toxic action on tumor cells. The correct approach must place emphasis upon the vascular and tissue reactions, which vary with animal species, tumors, and locations of the tumor. Negative results in rats, therefore, by no means exclude the usefulness of either arsenic or streptococcal toxin under properly chosen clinical conditions, as will be shown in a subsequent publication.¹⁸

CONCLUSIONS

1. The action of certain drugs, especially arsenic, and to a less extent lead, strikingly resembles that of local asphyxia and the mechanism of the tumor-killing effect may be similar. The attempts to use local ligations to obtain an intensified action of the drugs, or to use the drugs in local or systemic application to augment the effect of asphyxia, on the whole gave scanty success because of insufficient specificity, the distinctly increased injury to the tumors being offset by increased local or systemic dangers.

2. In conformity with previous work indicating that the tumor-killing action of local ligation is due neither to the direct asphyxia nor to the excess oxygenation of the ensuing hyperemia, the combination of ligation with various agents serving to increase or to depress cell respiration proved negative.

3. Notwithstanding the generally inconclusive results, some emphasis should be placed on the fact that cures with arsenic were obtained in some mouse

tumors and also in favorably situated rat tumors. There are undoubtedly differences in efficacy, depending upon the location and the specific sensitiveness of different tumors, and an application of this experience for an improved arsenic therapy of certain clinical tumors will be described elsewhere.¹⁴

EXPERIMENTAL UTEROTUBAL INSUFFLATION IN THE RABBIT*

A PRELIMINARY REPORT

HERBERT F. NEWMAN, M.D., NEW YORK, N. Y.

FALLOPIAN tube physiology has been investigated since 1925 by means of transuterine insufflation of gas according to the method of Rubin.¹ Essentially, this method consists of recording the fluctuations in pressure of gas insufflated through the uterus and tubes at a relatively constant rate. Feresten and Wimpfheimer² have demonstrated the similarity in the response of the rabbit and man to gas insufflation. In studying this field, one is immediately confronted with certain basic problems. How is the pressure curve affected by the type of gas employed, simple repetition of insufflation, rate of gas flow, intra-abdominal pressure, anesthesia, asphyxia, and number of functioning Fallopian tubes connected with the uterus? We have sought preliminary data to answer these questions.

METHOD

Virgin female rabbits, weighing 1 to 2 kg., were used. When anesthetized with nembutal, one grain per kilogram was injected intravenously, providing thorough anesthesia for thirty minutes, and, when the animals awoke, they remained quiet several hours for further investigation. The body temperature did not fall significantly throughout the experiments and no gross changes in cardiac and respiratory rates were observed unless the abdomen was permitted to distend too rapidly with gas.

Most of the experiments were performed by the technique of Feresten and Wimpfheimer.² A hypogastric incision was made and the body of one uterus was delivered into the wound. Through a small incision into the uterine wall, about 1 cm. proximal to the cervix, a cannula was directed cephalad and fixed by a ligature which encircled the entire circumference of the uterus to prevent gas from regurgitating through the cervix. The uterus and distal end of the cannula were replaced into the abdomen; the wound was temporarily closed with Allis clamps, and a small opening was made into the epigastrium to permit the free escape of gas.

Some studies were performed on animals with uterine fistulas made according to the technique of Reynolds.³ Under sterile precautions the vagina was drawn through a small suprapubic incision and divided. The distal portion of the vagina was ligated with silk to prevent peritoneal contamination with urine. The proximal end was drawn through a small stab wound in the midline, cuffed back and sutured to the skin to exteriorize the two cervices. These animals were insufflated without the use of anesthesia, using a clinical

*From the laboratory of the Sydenham Hospital, New York City.
Received for publication, April 2, 1940.

type of cannula with a rubber acorn to prevent the regurgitation of gas. One animal was insufflated daily for two weeks and post-mortem examination failed to reveal any evidence of uterine or pelvic infection.

The cannulae were connected to the usual clinical Grafix Kymographic Insufflation apparatus. This machine employs an anaeroid recording manometer which requires 48 c.c. of gas to record a pressure range of 200 mm. Hg. The clinically available mercurial float type of manometer was found less sensitive, requiring 62 c.c. for a similar pressure range. The insufflating gases were carbon dioxide and oxygen supplied from tanks at 15 pounds pressure. A valve permitted controlled variation in the rate of gas flow. Of necessity, the gas rate cannot be maintained truly constant because the flow rate during insufflation varied according to the pressure differential between the tank source of 760 mm. Hg and the recording kymographic range from 0 to 200 mm. Hg. Constant rates of flow, with pressure measured by an optical manometer, were obtained with fluid rather than with gas by means of a motor-driven syringe. The pressure changes with this medium did not resemble the usual gas insufflation curves and we are at present investigating the mechanism of this discrepancy.

To study the effect of death on insufflation, 30 c.c. of air were injected intravenously. The animal's respirations ceased immediately, and after several convulsive movements the animal became immobile. The heartbeat ceased several minutes later.

EXPERIMENTAL FINDINGS

In the analysis of a typical kymographic tracing, three features were studied: (1) The *primary pressure*, which is attained before gas enters the abdominal cavity, was manifest on the tracing by a characteristic maxima high peak followed by a precipitous fall until a plateau level is reached which is (2) the *general level of pressure*; this is maintained throughout an insufflation and about which (3) *small waves of pressure* fluctuate. These may be superimposed upon larger waves.

Effect of Different Insufflating Gases.—In this investigation the two biologically most important gases, carbon dioxide and oxygen, have been studied in most of the following experiments. Frequent differences have been observed between these gases. The effect of such inert gases as helium and nitrogen and the anesthetic gases are now under investigation.

Effect of Variable Rates of Gas Flow.—In an animal as small as a rabbit with a Fallopian tube luminal diameter of approximately 0.75 mm., small variations in the rate of flow of gas produced changes in the curves. A increase in the rate of flow generally raised the primary pressure level, the general level of insufflating pressure, the size and to a less extent the frequency of the small waves of pressure. At the very slow rates of gas flow some of the small waves of pressure may be submerged due to the low sensitivity of the manometer. Unless indicated, all further experiments were conducted with as constant a rate of flow as could possibly be maintained during a single experiment.

FIG 1.—Ten consecutive insufflations with oxygen

Effect of Repeated Consecutive Insufflations.—These animals were insufflated ten times consecutively with each insufflation lasting ten minutes and a rest period of twenty to forty-five seconds between tracings. Of twenty animals, oxygen was used in ten and carbon dioxide in the other ten; slightly different results were obtained.

1. The primary pressure at which gas enters the abdominal cavity generally becomes less on repeated insufflations, reaching the general level of insufflation pressure after about seventy minutes of insufflation. In one animal no gas entered the abdominal cavity on the first insufflation, although a pressure of 200 mm. Hg was reached; on subsequent insufflations the gas entered at progressively lower levels.

2. The general level of pressure also fell on repeated insufflations and remained comparatively stable after seventy minutes.

3. The frequency of the small waves usually decreased if carbon dioxide was used, although in a rare tracing the rate may return to that of the first insufflation. When oxygen was used, the frequency tended to remain more constant (Figs. 1, 2). With both gases the amplitude of the small waves tended to increase (Fig. 2).

4. In one animal, following insufflation of the right uterus for fifty minutes, the left uterus was insufflated. The tracing of the left uterus resembled more that of the first tracing of the right uterus than its fifth (Fig. 3).

Effect of Anesthesia.—Animals were insufflated without anesthesia or under procaine infiltration of the anterior abdominal wall and then reinsufflated after inducing anesthesia to compare the character of the tracings.

1. Nembutal produced no discernible effects in the dosage employed.

2. Ether anesthesia produced diverse effects depending on the gas employed. With carbon dioxide there was a gradual lowering of the general level of pressure and a diminution in the frequency and amplitude of waves (Fig. 4). Often under deep ether narcosis, the manometer recorded zero with no waves. When oxygen was used, the tracing remained normal with the exception of a marked rise in the general level of pressure, even though the animal may be anesthetized to the point of death. This suggests that anesthesia might play a role in the clinical diagnosis of apparent "closed tubes."

Effect of Increased Intra-abdominal Pressure.—Moderate and even marked abdominal distention, if produced gradually (as by obturating the vent in the upper abdomen and permitting the insufflated gas to remain in the abdominal cavity), had no effect upon the curves. The changes produced in intra-abdominal pressure by quiet respiration produced no observable changes in the tracings. However, a sudden increase in intra-abdominal pressure always caused the small waves to fluctuate about a higher general level of pressure. Exciting the unanesthetized animal by pinch stimulation of the ear caused a sudden rise in intra-abdominal pressure and a rise in the general level of pressure recorded on the kymograph. When the abdomen was opened widely to expose the cavity to free atmospheric pressure, repeated stimulation of the ear caused no change in the tracing (Fig. 5).

Fig. 2.—Five consecutive insufflations with oxygen, demonstrating the progressive rise in height of the waves.

Fig. 3.—Comparison between the first tracing of the left uterus and the first and fifth consecutive tracings of the right uterus.

Fig. 4.—Effect of ether anesthesia on an animal insufflated with carbon dioxide with control period of rest.

Fig. 5.—Effect of excitation with closed and open abdomen in an animal insufflated with carbon dioxide.

Fig. 6.—Insufflation with oxygen in an animal asphyxiated with excessive nembutal and the change in the tracing upon death of the animal.

Effect of Asphyxia.—In the case of two animals insufflated with carbon dioxide, the dosage of nembutal was apparently excessive, and asphyxia, evidenced by cyanosis and infrequent, shallow respirations, resulted. In these cases very deep and slow undulating waves replaced the usual quick shallow waves of pressure.

An asphyxiated animal, insufflated with oxygen, presented a similar type of curve, but as soon as its heart stopped beating, the tracing returned to a normal variety (Fig. 6). This suggests that an excessive blood carbon dioxide may change the character of the waves.

Insufflation of Dying and Dead Animals.—As soon as respirations of the animals ceased, even though the abdomen was kept open to obviate the effect of increased abdominal pressure induced by the convulsive movements, the general level of insufflating pressure rose to huge heights. When carbon dioxide was used, the curve gradually fell to low levels, with irregular small waves and, on cessation of the heartbeat, the pressure fell to zero and all small waves disappeared (Fig. 7).

When oxygen was used, the characteristic agonal high pressure level was observed and then the pressure fell gradually to a normal level and a normal curve resulted and was maintained for more than twenty-five minutes, although in one animal, the heart had been removed and its lumbar spine transected to produce practically an *in vitro* preparation.

Insufflation with either gas of animals that had been dead for a long time failed to elicit any contractions or any rise in the tracing unless the gas was passed at very rapid rates of flow, when the resultant tracing merely represented the pressure relations produced by the passage of gas through narrow, inanimate channels.

Effect of Simultaneous Insufflation of Both Uteri.—The insufflation of the human uterus with its single cavity and two tubes or the simultaneous insufflation of both uteri in a rabbit suggests two theoretical dynamic possibilities:

1. The resultant tracing is actually produced by gas passing through only one tube.
2. The gas passes through both tubes. This latter possibility brings up the question as to whether the two tubes contract and relax synchronously.

In each of two rabbits both uteri were cannulated and connected by a Y tube to the insufflation apparatus. By appropriate clamps on the tubing each uterus was insufflated in turn and finally both simultaneously. During the bilateral insufflation the gas was observed to bubble from only one tube, the one whose primary pressure level of gas entrance was the lower (Fig. 8).

Kiag⁴ with the aid of a double stethoscope reported that in insufflation of human beings, the gas passed either through one or the other tube or through both at once. The pneumoperitoneum produced by insufflation in man has been frequently unilateral. If the gas were to pass through both tubes, the resultant curves in man should exhibit greater variation in the amplitude and frequency of the small waves, with increasing asynchrony of the tubes. Further investigations along this direction are being performed in man.

Fig. 7.—Effect of intravenous air upon an animal insulated with carbon dioxide.

Fig. 8.—Insulation with carbon dioxide of a bilaterally extirpated animal, demonstrating control tracings for such a case and subsequent bilateral insulation.

CONCLUSIONS

1. The type of the curve varies slightly with the kind of insufflating gas.
2. The flow of gas must be kept constant and adequate for the sensitivity of the manometer.
3. Inasmuch as repetition of insufflation modifies the character of the curve, definite criteria must be established to evaluate the curves obtained under experimental conditions as in the investigation of drug and hormonal action.
4. Various anesthetics exert different effects upon the kymographic curves.

I wish to acknowledge the kind advice of Dr. Max Mayer and Dr. Arthur Ginzler and the technical assistance of Mrs. Elizabeth Dreifus.

TREATMENT OF POLYCYTHEMIA VERA WITH LIVER AND CHOLINE HYDROCHLORIDE*

OVID O. MEYER, M.D., AND ETHEL W. THEWLIS, MADISON, WIS.

DAVIS¹ has recently reported that polycythemia induced in dogs by exercise on a treadmill, exposure to reduced pressure in a chamber, or by the administration of cobalt was modified significantly with reduction in the numbers of erythrocytes when whole raw liver or liver extract was administered. In the dogs made polycythemic by cobalt administration or reduced pressure the oral administration of choline hydrochloride, 8 mg. per kilogram in 1 per cent solution per day, also caused diminution in the erythrocyte count after two or three doses.

The mechanism of the production of polycythemia with cobalt is not established with certainty, but it is probably a result of bone marrow stimulus without a physiologic need for this stimulus. The polycythemia of exercise is, of course, but relative, whereas that of reduced pressure is compensatory for a diminished oxygen tension. Therefore, it seemed singular that the same type of therapy could cause reduction in the number of erythrocytes in all three types. Nevertheless, in view of the reported results and the suggestion of Davis that choline may be of benefit in treating polycythemia vera, 5 patients, none of whom had received any previous treatment of any kind for their primary disease, were given either whole raw liver, choline hydrochloride, or both. Raw liver is a good source of choline, containing not less than 1 per cent.²

Plasma, blood volume (c.c.)	2,784		2,300				3,912	4,542	2,970	
Total blood volume (c.c.)	7,579		6,084				13,321	12,784	9349	
Patient's weight (kg.)	63.5		56.3		71.0		72.6	65.4	68.2	
	Received 300 Gm. of raw ground liver daily for 10 days		Received 300 Gm. of raw ground liver daily for 19 days		Received 300 Gm. of raw ground liver daily for 14 days		Received 300 Gm. of raw liver daily for 32 days		Received 600 mg. of choline hydrochloride daily for 9 days after initial dose of 300 mg.	
									Received 550 mg. of choline hydrochloride daily for 12 days after initial dose of 250 mg.	

METHODS

All patients had complete blood counts done; the erythrocyte counts in duplicate, hemoglobin determinations using the Haden-Hausser hemoglobinometer (15.4 Gm. per 100 c.c. equaling 100 per cent); reticulocyte counts on stained smears, the percentage being derived from examining 1,000 erythrocytes; hematocrit determinations using Wintrobe tubes, and blood volume determinations (in four of the five patients as further diagnostic data by the method described by Gibson and Evelyn³). The total and differential leucocyte counts are not reported since there were no significant alterations during treatment in any case.

In patient 2, the only one followed as an outpatient, blood studies were done previous to therapy and again at its completion. In the other four patients complete blood counts, reticulocyte counts, and hematocrit determinations were done twice each week throughout each period of observation. For brevity's sake, however, only the data acquired before therapy and at the completion of each period of study are given.

Each of the four patients treated with liver received 100 Gm. of fresh ground raw calf's liver with salt, pepper, and catsup added, or in fruit juice, three times a day. The patients who received choline hydrochloride got 8 mg. per kilogram body weight in 1 per cent solution. The five patients were males and their respective ages were 64, 51, 54, 20, and 59. They all took choline hydrochloride and liver with little or no difficulty.

DISCUSSION

The results appear to be clearly negative in four patients as far as reduction of erythrocytes or hemoglobin is concerned, for there was no significant change in any patient while undergoing liver or choline therapy. In patient 3, who received liver therapy, there was a decrease in hemoglobin and erythrocytes, and in the hematocrit reading. This diminution had its inception on the tenth day of treatment and was of the same degree on the fourteenth day. During the period of observation, before a fall in the blood levels was demonstrable, a wet granular ulcerative lesion on the leg was present. Coincident with changes in the blood, complete healing occurred. Whether hemoconcentration may have played a part in explanation of the previous very high hemoglobin and erythrocyte levels is problematical. Attempts at determining the blood volume preceding therapy were unsuccessful since pronounced viscosity of the blood and prompt coagulation interfered with collection of blood samples.

Marshall⁴ has reported that cobalt polycythemia in rats is modified with reduction in the erythrocyte count following liver extract or ventriculin administration but not after feeding fresh whole liver. Stephan⁵ has reported that whole fresh liver was of clinical value in treating the polycythemia symptomatic of a variety of conditions, but Major⁶ noted no benefit from liver extract administration in three cases of polycythemia vera. We have treated no case of polycythemia with liver extract. Ogawa⁷ successfully treated one case of polycythemia vera with oral and parenteral liver substance, but the polycythemia recurred with the cessation of therapy.

Our results with liver therapy in polycythemia vera are not absolutely conclusive for during therapy one patient showed a decrease in erythrocytes and

hemoglobin, although there was an extenuating circumstance in this case. In the other two patients treated with raw calf's liver alone, in the one patient treated with liver and later with choline hydrochloride, and in the one patient treated with choline alone there were no significant changes in the blood levels. It is our interpretation that the administration of raw calf's liver or choline hydrochloride is probably without value in the treatment of polycythemia vera.

We wish to acknowledge the kind cooperation of Dr. Marian S. Kimble who did the blood volume determinations.

FURTHER STUDIES ON THE EFFECT OF MASSIVE INTRAVENOUS INFUSIONS IN NARCOTIC POISONING*

THEODORE KOPPANYI, PH.D., AND REGINALD A. CUTTING, PH.D., M.D.
WASHINGTON, D. C.

IN A PREVIOUS communication¹ we described the effects of massive intravenous infusions of isotonic glucose or saline solutions, in volumes varying from one-fourth to three-fourths the body weight, on the duration of barbiturate narcosis. It was found that infusions of such volumes of fluid accelerated the time of recovery of anesthetized animals and prevented death in those receiving fatal or several fatal doses of these drugs. It was suggested that the method of treatment with massive intravenous infusions may similarly prove antidotal to all slowly acting neurotoxic drugs, particularly central depressants. The present report deals with the experimental exploration of this hypothesis.

Dogs were used in all the experiments. For the technique of administering massive intravenous infusions reference should be made to the preceding paper.¹ A solution of 1 per cent sodium chloride was used for infusions in this series. It should be emphasized in this connection that care in the technique of the preparation of solutions to be infused in quantities such as we have used

*From the Departments of Pharmacology and Materia Medica and Physiology, Georgetown University School of Medicine.
Received for publication, April 10, 1940.

is essential. This is to avoid the possibility of contamination with pyrogenic agents and other harmful contaminants possibly present in water. Scrupulous asepsis should be observed throughout, and the rates of infusion should be carefully controlled. One of the principal mechanisms likely to cause fatalities from massive infusions is insufficient diuresis. It is the retained fluid, rather than the total amount infused, which is critical. Animals withstand more rapid rates of infusion and larger total quantities of solution when the kidneys eliminate urine in considerable quantities. The effect of massive infusions was tested on the course of poisoning by oral, hypodermic, or intravenous fatal doses of the following substances: methyl alcohol, ethyl alcohol, chloral hydrate, sodium bromide, and potassium arsenite. Whenever oral doses were given, the animals also received a preliminary injection of 10 mg. per kilogram of body weight of morphine sulfate* intramuscularly to abolish the vomiting reflex and thus insure retention of the dose. Inasmuch as morphine is a well-known synergist to all aliphatic narcotics, one may assume that morphine enhanced the toxicity of the orally administered drugs.

Many animals not listed in the following discussion and tabular protocols were used during the course of the experiments. For every dose of methanol, ethanol, chloral hydrate, and sodium bromide here reported, doses of similar magnitude were administered to two or more animals which died before infusion could be instituted, and others receiving such doses died during the infusions. All these may be regarded as constituting control experiments and as supporting the observations of other investigators that all doses used were considerably in excess of the ordinary fatal dose.

Methanol.—Methanol was administered by mouth in two animals thirty minutes following a preliminary injection of morphine to control vomiting. Absolute methanol in doses of 20 c.c. diluted with water was given to each animal. No regurgitation or vomiting occurred. The intravenous infusion was started as soon as the animals' righting reflexes were lost. Subsequently the animals showed complete anesthesia and muscular relaxation. Following the infusion the animals were kept in warm metabolism cages until recovery was complete. Both animals recovered. The index of recovery was the ability of the animal to stand unsupported. The average oral fatal dose of methanol in dogs is 10 c.c. Thus these animals survived two fatal doses.

One animal received 10 c.c. of methanol dissolved in 1 per cent sodium chloride solution by slow intravenous infusion over a period of forty-three minutes, becoming anesthetic after half of the dose had been injected. This dog recovered in about thirty-six hours. The urine excreted by this animal following injection of the alcohol was of a deep red color, evidently the result of hemolysis.

No evidence of blindness was seen in any of these animals though they were observed for several weeks after recovery.

Ethanol.—Ethanol was administered to two animals orally and to one animal intravenously, as described for methanol. One animal, receiving 15 c.c.

*All doses are expressed in terms of milligram, gram, or cubic centimeter per kilogram of body weight. To avoid repetition the phrase "per kilogram of body weight" will hereafter be omitted.

of ethanol by mouth, recovered, and one, receiving 20 c.c. by mouth, died. A dog receiving 12 c.c. intravenously recovered. The average oral fatal dose of ethanol for dogs is 9.6 c.c.

Chloral Hydrate.—Chloral hydrate was administered in aqueous solution to one animal subcutaneously and to two animals intravenously. The technique employed was the same as that described for methanol. The mean subcutaneous fatal dose of chloral hydrate is 600 mg., whereas 500 mg. are fatal by intravenous injection. Inasmuch as considerably more than this amount was administered, the results may be regarded as significant.

Sodium Bromide.—Sodium bromide in doses of 5.0 Gm. and 7.5 Gm. was administered to each of two dogs in the following manner: The animals were immobilized in plaster of Paris bandages. Under local anesthesia the external jugular vein was exposed and cannulated. An intravenous infusion of 1.5 per cent sodium bromide solution (isotonic) was then given in predetermined dosage. Beyond this point 1 per cent sodium chloride solution was substituted. Although both animals recovered, they showed somnolence for several days and shed quantities of hair; portions of their skin became practically denuded, and deep ulcers developed on various parts of their bodies, particularly over bony prominences. The mean fatal dose of sodium bromide is 3 Gm.

Potassium Arsenite.—Each of five animals was given 2 c.c. of potassium arsenite solution (U.S.P. XI) by mouth. Two of these animals received massive intravenous infusions, the remaining three served as controls. All five animals died. All animals, including those which received massive infusions, lapsed into coma, developed muscular spasms, and died within about the same time. It is concluded, therefore, that massive intravenous infusions had no effect on the course of acute arsenical poisoning. Table I summarizes the results of all experiments previously described.

*These animals excreted in the urine from 20 to 30 per cent of the infused fluid during the course of the infusion, and from 40 to 90 per cent within twenty-four hours.

COMMENT

In our previous communication¹ we discussed the probable mechanism of the antidotal action of massive intravenous infusions in acute barbiturate poisoning. We expressed the opinion that this action is dependent upon the ability of the infused solution to take up a part of the drug, which otherwise would accumulate in toxic concentration in nervous tissues, and to distribute it among the tissues of the body not specifically affected by the drug. When the infused fluids are excreted by the kidneys, the urine contains the neurotoxic poisons in high concentrations, higher than exist in any of the tissues of the body. These considerations apply to neurotoxic poisons because the central nervous system, in contrast to other tissues, does not become hydrated as a result of massive infusions.² The experiments herein described show that the results obtained with barbiturates can be duplicated in the case of three other aliphatic narcotics and sodium bromide, but not in inorganic arsenical poisoning, because arsenic is not primarily a neurotoxic agent and behaves rather as a general protoplasmic poison.

In conclusion, we feel justified in repeating our recommendation for the clinical use of large intravenous infusions in the treatment of alcohol comas, and acute chloral hydrate and bromide poisonings, though not necessarily in the extremely energetic form used in these experiments. Massive infusions should prove less effective or probably not effective in poisoning with general protoplasmic toxins. This treatment is not proposed as a replacement for the rapidly acting analeptics in narcotic poisoning, but rather as an adjuvant. It may be of particular value in cases in which patients do not show a satisfactory response to the analeptic treatment.

CLINICAL CHEMISTRY

PLASMA VOLUME AND PLASMA PROTEIN CONCENTRATION AFTER SEVERE HEMORRHAGE*

D. BAILEY CALVIN, M.A., PH.D., GALVESTON, TEXAS

RESEARCHES recently reported^{1, 2} have suggested a possible increase in total circulating plasma protein following shortly after severe hemorrhage. From work previously reported from this laboratory, it is known^{3, 4} that in hydremic plethora extra protein may enter the vascular system from some source in the body, possibly the liver.⁵ Similar changes have been observed with increased plasma volume, following the use of diuretics in the treatment of the edema of circulatory failure and cardiac decompensation.⁶ The present report deals with this problem of protein mobilization in hemorrhage, employing the newer techniques for plasma volume determination.

EXPERIMENTAL

Large dogs were used. Three types of preparation were employed. (A) Dogs without food or water for forty-eight hours prior to hemorrhage. (B) Dogs allowed water but no food twenty-four hours prior to hemorrhage, then given 500 ml. of 0.7 per cent sodium chloride solution by mouth one hour prior to hemorrhage. (C) Dogs allowed water but no food twenty-four hours prior to hemorrhage, with injection into the jugular vein of a volume of 0.9 per cent sodium chloride equivalent to the volume of whole blood withdrawn, immediately after withdrawal.

The hemorrhage from the carotid artery was 25 per cent of the dog's blood volume (as previously determined) within five minutes.

Plasma volumes were determined by the Gibson and Evelyn⁷ techniques; total proteins by the Kjeldahl method; hemoglobins according to Cohen and Smith;⁸ albumins by the Howe,⁹ and later by the Campbell and Hanna¹⁰ methods. Mayo 6 ml. tubes at 3,000 r.p.m. for thirty minutes were used for cell volumes.

RESULTS

A total of 11 dogs was used, 4 in group A, 4 in group B, and 3 in group C. Typical data are presented graphically in Figs. 1 A and B, and Fig. 2, C.

The animals in group A were very dehydrated. This condition is reflected in the posthemorrhage blood picture. There is a slow fall in hemoglobin and per cent of plasma protein. In contrast to these changes, there is a slow rise in plasma volume, and a similar but slightly faster rise in total circulating

*From the Department of Biological Chemistry, University of Texas School of Medicine, Galveston.

Received for publication, July 27, 1940.

plasma protein (plasma volume/100 \times Gm. protein per 100 ml.). This extra fluid and protein must come from the tissue (or lymph), the protein entering in solution with the water. The changes observed in group A were never so great as for the conditions to be described in B and C, ranging from about 10 to 20 per cent replacement of the total protein removed in hemorrhage.

Fig. 1.—A, Hemorrhage after forty-eight hours food and water fast. B, Hemorrhage after twenty-four hours water fast, 500 ml. of 0.7 per cent sodium chloride per os one hour prior to hemorrhage.

In group B the dogs were somewhat dehydrated, but in fair water balance. To this adequate body fluid was added 500 ml. of saline solution, given by mouth, one hour prior to hemorrhage. The one-hour period was selected because of a previous finding³ that injected saline reaches a point of maximum storage in the tissues from sixty to one hundred minutes after intravenous administration. Very little or no diuresis occurred. Thus the body fluids available for posthemorrhage blood volume compensation were at a maximum.

The greater availability of fluid is amply demonstrated in Fig. 1 B. The hemoglobin drops more sharply than in group A. This is also true of plasma protein concentration (per cent). The plasma volume, on the other hand, does not fall off so rapidly, indicating a very rapid inflow of fluid from the inter-

stitial spaces. As in group A, so also here to a more marked degree, this inflowing fluid brings with it considerable amounts of protein, as measured in terms of total circulating plasma protein.

Fig. 2.—C, Hemorrhage after twenty-four hours water fast. A volume of 0.9 per cent sodium chloride equivalent to the volume of blood removed is injected into the jugular vein immediately after hemorrhage.

The animals in group C were in similar fluid balance to those in B, prior to per os saline administration. Immediately after hemorrhage was complete, a volume of 0.9 per cent sodium chloride, equivalent to the volume of blood removed, was injected rapidly into the jugular vein. The initial rapid changes prior to injection of saline were similar to, but somewhat less than, those in group B. After saline injection, however, marked falls in hemoglobin and in per cent plasma protein occurred.

The plasma volume changes were of much interest. From the low value after hemorrhage the volume actually rose above the normal level. However, this condition held only momentarily. As was to be expected from previous data on hemorrhage control,¹¹ the injected saline left the vascular system rapidly and to a considerable extent, resulting in a fall in plasma volume. This condition obtained for upward of an hour, at which time the plasma volume showed a tendency to rise.

During the whole of this period, and more markedly in the first few minutes, extra protein entered the vascular system, as evidenced by the initially rapid, then gradual, rise in total circulating plasma protein.

In all groups, the albumin : globulin ratio rose following hemorrhage.

DISCUSSION

The results here presented must not be confused with those obtained in acute hemorrhage or after plasmapheresis. The degree of hemorrhage used (25 per

cent of the determined blood volume) was not sufficiently severe to upset physiologic equilibrium in the dog. An effort was made to avoid gross evidence of shock. No animals were lost as a result of the procedure. There was, however, some blanching of the buccal membranes, and the heart rate was increased to some extent. Blood pressures were not measured.

Thus the animals were able to affect a rather satisfactory recovery by normal, rapid physiologic response. It is remarkable to note the degree to which this can be accomplished. In one dog, group C, 14.7 Gm. of plasma protein were removed. Within thirty minutes 6.5 Gm. of this had been replaced, and at the end of four hours more than 50 per cent of the plasma protein loss had been taken care of by tissue contribution of storage protein. These values are in line with others obtained in dogs after injections of hypertonic solutions,⁴ where an increase as great as 20 per cent has been observed to occur along with the resultant increase in plasma volume.

The albumin:globulin ratio is of significant interest. This ratio rose in all cases following hemorrhage. The extent of the rise depended upon the degree of total compensation affected in plasma protein, being higher when the increase in total circulating plasma protein was greater. This would seem to indicate, therefore, that the protein entering the vascular system under this condition of stress was composed mainly of albumin. These results are similar to those for hydremic plethora⁴ and those following edema reduction by diuretics.⁶

The exact mechanisms for the changes noted are hard to evaluate. The lymph certainly may serve as one source of this protein and fluid increase. Indeed, evidence has been given for an increased lymphatic flow following similar conditions. The rate of change observed, however, would seem to make it necessary to assume some degree of backflow through the capillaries both of fluid and protein in order to explain the experimental results. Recently, Drinker¹² gave some support to this idea.

The matter of source of protein for the observed increases is not difficult to explain. The liver is known to produce at least part of the protein necessary for plasma protein regeneration. Considering the size of this organ, the slow rate of circulation through it, and the relatively small demand on the whole body made by the replacement of 15 to 20 Gm. of plasma protein, the experimental findings are not untenable. Furthermore, when consideration is given to the total mass of protein in the body, this small amount might easily be accounted for physiologically without being detectable by analytic chemical methods.

It is logical to assume, therefore, on the strength of the data presented, that the body is capable of supplying, rapidly, considerable amounts of protein for the replacement of losses due to hemorrhage, so long as actual gross shock does not intervene. Replacement of fluid depends upon available interstitial supply of water and salts for this purpose.

SUMMARY AND CONCLUSIONS

1. Following subacute hemorrhage in dogs, there is a compensatory movement of fluid from the tissues to the plasma.
2. The degree of compensation depends, in large measure, on the water balance of the body prior to hemorrhage.

3. Proteins enter the vascular system along with the fluid.
4. The protein entering the vascular system is primarily albumin.

PHENOLPHTHALEIN STUDIES: THE RATIO OF FREE TO TOTAL PHENOLPHTHALEIN IN THE URINE*

ITS INFLUENCE UPON THE "WOLDMAN TEST"

F. STEIGMANN, M.S., M.D., AND J. M. DYNIEWICZ, Ph.C., CHICAGO, ILL.

IN OUR preliminary report¹ which was based on 200 cases (34 normal persons and 166 diseased patients) we found Woldman's test positive in 41 per cent of the normal individuals, in 78.5 per cent of the gastrointestinal cases, and in 82.7 per cent of other types of disease, including jaundice. Our result of positive Woldman tests in 41 per cent of the normal persons is perhaps somewhat higher than the percentage in similar cases obtained by others. On the other hand, however, we also obtained higher positive results in gastrointestinal cases (78.5 per cent) as compared to results by others, e.g., 72 per cent. The high incidence of positive results in our series may be attributed to meticulous interpretation of color changes.

*From the Departments of Pharmacology and Therapeutics and of Medicine, University of Illinois College of Medicine, and the Cook County Hospital, Department of Medicine, Chicago. Assisted by a grant from Phenolphthalein Research, Inc., under the direction of Dr. Bernard Fantus.

Our original observation that the urinary elimination of free phenolphthalein is no test for gastrointestinal ulceration has been confirmed not only by further studies in our laboratories but also by reports from various other clinics. Thus Kremer and others² in a study of 137 cases conclude that the Woldman test may be valuable as an adjunct in diagnosis, but that more must be learned of the physiology involved before it can be considered reliable as a simple test for the determination of gastrointestinal lesions.

Suttenfield,³ from his study of 94 cases, concludes that the proposed phenolphthalein test is of no value in differentiating gastrointestinal disease from other diseases, nor organic from functional intestinal diseases.

In a study of 203 patients Banks⁴ found the test negative in one-fourth of his cases with proved gastrointestinal disease, and positive in one-sixth of the controls. He believes that the test has too wide a range of error to be considered reliable in the diagnosis of gastrointestinal disease.

In his series of 105 individuals Notkin⁵ obtained negative Woldman tests in over 30 per cent of his cases with active gastrointestinal lesions. He also discovered variations from negative to strongly positive in the same patients when the test was repeated at appropriate intervals. He concludes, therefore, that the Woldman phenolphthalein test does not constitute a test for the presence of gastrointestinal lesions.

LeVine,⁶ from a study of 115 cases, concludes that the phenolphthalein test cannot be relied on to prove or disprove the presence of a lesion in the mucous membrane of the gastrointestinal tract.

Slutzky and Wilhelmj,⁷ from experiments on dogs, believe that the variability of their results would seem definitely to exclude the phenolphthalein test as a test for determining the presence of ulceration of the gastrointestinal tract.

Rowland,⁸ however, believes that not enough observations have been done to negate the test completely. In his defense of this test, however, appear certain concepts of phenolphthalein absorption, conjugation, and elimination which are not in accordance with our observations on these facts gained through a study on hundreds of cases during a period of four years. This paper has, therefore, been written with the idea of clarifying some of the more important data about the fate of phenolphthalein in the body: data which may indirectly help in the better understanding of the facts underlying and influencing the Woldman test.

RAPIDITY OF ABSORPTION

Woldman's test is based upon the thesis that, if there is an ulcer in stomach or bowel, ingestion of phenolphthalein in rapidly absorbable form (alcoholic solution) will permit the finding of free phenolphthalein in the urine because the break in the mucosa allows phenolphthalein to enter the circulation more promptly. It is obvious that we cannot compare the results of the quantitative studies done previously by Fantus and Dyniewicz,⁹ and quoted by Rowland, with the results now being discussed. There is a much greater and prompter elimination of phenolphthalein after the alcoholic dose of phenolphthalein than after the same or even larger doses given in capsule form. The time factor in the two studies was also different. In the "Woldman's test" studies the speed of

elimination is measured at two-hour intervals for ten hours, while in the Fantus and Dyniewicz studies interest was centered in the total elimination as shown by collections of twenty-four-hour specimens.

The previous work on phenolphthalein elimination was done after ingestion of doses ranging from 0.10 Gm. to 0.25 Gm. in capsule form. The total elimination was studied for as long as six days. The elimination of from 1.41 to 19.7 per cent was for all doses. That many factors influence the elimination of phenolphthalein in the urine was recognized at that time and set forth in the article, e.g., "the larger the dose the smaller the percentage of the elimination" and "the greater the laxative action the less the elimination." We now are aware of additional causes which influence the amount of phenolphthalein eliminated in the urine, e.g., low elimination in kidney disease and high elimination in "yellow" block (jaundice) and in "white" block (sepsis). There is, of course, a great difference in phenolphthalein elimination when the drug is taken in alcoholic solution or in capsule form. When 100 mg. of phenolphthalein in an alcoholic solution are taken on an empty stomach, we obtain on the average 24 mg. per cent of total phenolphthalein in the stool and 38 and more per cent in the urine. After the ingestion of 300 mg. of phenolphthalein in a capsule, an average of 75.5 per cent of the dose was found in the stool and only 8.9 per cent on the average in the urine. The reason for the apparent discrepancy between our present results and some of the data in our former reports is, therefore, plain.

TABLE I

NO. OF SPECIMENS	FREE PHENOLPHTHALEIN PRESENT IN URINE (MG. %)	AVG. CONC. OF CONJUGATED PHENOLPHTHALEIN PRESENT IN URINE (MG. %)
162	0.0	1.31
63	0.05	2.55
62	0.15	5.0
27	0.25	7.4
12	0.35	7.6
12	0.45	9.6
29	More than 0.45	11.0

When one desires to favor absorption of phenolphthalein and does not give it for cathartic action, its administration by the method suggested by Woldman, e.g., in alcoholic solution on an empty stomach, eliminates at least three variable factors: the phenolphthalein is not dependent for solution upon the secretions of the intestines; a more uniform and more rapid absorption occurs, since there is no food interference; and the alcoholic vehicle helps absorption from the stomach. Furthermore, by studying the phenolphthalein elimination at two-hour instead of twenty-four-hour intervals, the amount of phenolphthalein in the urine is much less likely to be influenced by the extent of laxative action, which usually occurs after six hours.

The ten-hour elimination after the alcoholic dose of phenolphthalein frequently exceeds the amount eliminated in six days after the same dose given in capsule form, and consequently the finding of free phenolphthalein is that much more common, as this depends upon two factors: the quantity of total phenolphthalein in the urine, and the bacterial decomposition of the conjugated phenolphthalein.

RELATION OF FREE TO CONJUGATED PHENOLPHTHALEIN

The amount of free phenolphthalein found in the urine is largely influenced by the quantity of conjugated phenolphthalein present (as is shown in Table I and Graph 1).

It must, of course, be understood that every specimen having a concentration, e.g., of 5 mg. per cent of conjugated phenolphthalein does not give a positive test for free phenolphthalein, neither does every specimen having a lower concentration of conjugated phenolphthalein give a negative test for free phenolphthalein. But the general tendency is in this direction (see Graph 1).

Bacteria greatly influence the presence of free phenolphthalein in the urine by causing decomposition of conjugated phenolphthalein to free phenolphthalein on mere standing. Urine containing conjugated phenolphthalein and incubated at 37° C. will show a progressive increase in free phenolphthalein. The same urine kept in the refrigerator or passed through a Seitz filter and then incubated will not show this breaking down of conjugate. Hence prompt testing of the urine is an essential part of the Woldman test.

As previously stated, the data presented mean that "the amount of conjugated phenolphthalein in the urine generally governs the presence or absence

of free phenolphthalein. Hence, any condition which will promote an increased formation or circulation in the blood of conjugated phenolphthalein will lead to the appearance of free phenolphthalein in the urine." It is correctly pointed out, as originally stated by us, that in contrast to the patients only 1 per cent of normal persons show free phenolphthalein when the concentration of conjugated phenolphthalein ranged from 1 to 2 mg. per cent, and that only few normal persons show a concentration of conjugated phenolphthalein of above 5 mg. per cent. It is not the 20 to 40 per cent of positive tests in so-called normal individuals which make the Woldman test unreliable, but the 82 per cent of positive results in diseases other than gastrointestinal. *It is this latter fact of over 80 per cent positive Woldman's tests in nonalimentary tract diseases, which renders this test unreliable for diagnosing an ulcerative lesion in the gastrointestinal tract.* Since ailing individuals are the ones who will be subjected to the test, it is important to note how many patients show free phenolphthalein within the range of 1 to 2 mg. concentration of conjugated phenolphthalein and how many of them have a concentration of conjugated phenolphthalein above 5 mg. per cent. In our study with hospital patients, free phenolphthalein was found in 36 per cent of the specimens when their conjugated phenolphthalein concentration was 1 to 2 mg. per cent, and 46 per cent of the specimens showed a conjugated phenolphthalein concentration above 5 mg. per cent. It is thus clear that the excretion of phenolphthalein in normal persons has actually no bearing in the controversy about the usefulness of the Woldman test in ill patients.

INFLUENCE OF DISEASE

Disease has, however, a most marked influence upon the elimination of free phenolphthalein in the urine. Even certain "mild" affections of the individual, e.g., cold, sore throat, may greatly change phenolphthalein elimination. As previously stated, in kidney disease there may be practically no phenolphthalein in the urine, while in jaundice very little may be found in the stool and as much as 80 per cent in the urine.

The statement "All observers recognized early that cardiovascular renal disease and blood dyscrasias gave a high per cent of positives" can be only partly confirmed by our results. Cardiovascular diseases and blood dyscrasias give a high percentage of positives. Nephritic patients, however, gave in our series the smallest percentage of positives (Table I of preliminary report¹) since they do have a very small elimination of conjugated phenolphthalein. Rowland's interpretation of the positive Woldman's tests in cardiovascular disease, based on the investigations of Portis and Jaffe,¹⁰ who concluded that: "When peptic ulcer is the incidental lesion, it is most often associated with cardiovascular disease," seems logical and should be further investigated. It, however, does not explain the high incidence of positives in the blood dyscrasias and jaundice.

From the findings in our studies we must disagree with the following statements by Rowland: "The conjugation of phenolphthalein with sulfates, glycuronates, or other substances is believed to occur in the liver. This function seems to be suspended in jaundice and free phenolphthalein regularly appears in the urine." It is our experience that in jaundice the amount of conjugated phenolphthalein in the urine is two to four times that of the normal,

a fact which we believe to be the cause of the regular appearance of free phenolphthalein in the urine. Quantitatively the concentration of conjugated phenolphthalein to total phenolphthalein was found to be about 95 per cent in jaundiced individuals. In other words, in jaundice, free phenolphthalein appears regularly in the urine, not because conjugation of phenolphthalein in the liver is suspended (it may even be questioned whether phenolphthalein is conjugated in the liver), but because the urine contains very large amounts of conjugated phenolphthalein.

It is easy to perceive how false positive tests can be obtained in jaundiced cases, when qualitative examinations are performed. This possibility, however, is excluded when quantitative studies are done, as in these the phenolphthalein is extracted by ether and then determined colorimetrically.

Negative Woldman tests may occur when the solution of phenolphthalein is not absorbed from the stomach or intestine, or when absorption is delayed by other than intragastric or intraintestinal factors, since in those instances even a decrease of conjugated phenolphthalein is found in the urine. Work on the factor of absorption is presently going on in our laboratory and promises to give interesting results.

CONCLUSIONS

1. Additional studies on phenolphthalein elimination support the preliminary observation that the higher the concentration of conjugated phenolphthalein in the urine, the more likely the appearance of free phenolphthalein in it.
2. Phenolphthalein elimination after ingestion of 100 mg. of phenolphthalein in alcoholic solution is much greater within ten hours than the elimination after 300 mg. of powdered phenolphthalein in capsule within twenty-four hours.
3. This difference is obviously due to the factor of absorption.
4. Reports in the literature confirm our observation that Woldman's test¹¹ is unreliable as a test for gastrointestinal ulcerations.

We wish to express our thanks to Dr B. Fantus for his valuable suggestions and to Miss E. Redding, R. N., for her technical help.

THE EFFECT OF SULFANILAMIDE ON ACID-BASE BALANCE*

EVAN W. MCCHESENEY, PH.D., KIMBALL D. SPRAGUE, A.B.,
AND IRVINE H. MARSHALL, M.D., RENSSELAER, N. Y.

SINCE the introduction of sulfanilamide in 1937, many important problems concerning its physiologic effects have been adequately studied. However, one significant aspect of the picture remains in a state of confusion; this concerns the effects of the drug on the acid-base balance of the organism. Although it was rather early recognized¹ that administration of the drug produces a condition simulating acidosis—at least in the sense that there is a decrease in the carbon dioxide combining power of the blood plasma—there has not been a complete agreement among different investigators as to the nature of the disturbance in acid-base balance or its cause.

Observations made on patients¹⁻⁵ indicate that administration of sulfanilamide (doses usually 3 to 10 Gm. per day) causes: (1) a decrease in the plasma carbon dioxide combining power, and (2) an increase in urinary carbon dioxide and pH. The same phenomena were observed in dogs by Marshall, Cutting, and Emerson,⁶ the doses being from 0.5 to 2 Gm. per kilogram of body weight per day. Thus it is clear that bicarbonates are being lost from the blood and are being excreted in the urine. The general tendency has been to regard the disturbance in acid-base balance due to sulfanilamide therapy as an acidosis, and to supplement such medication with sodium bicarbonate or lactate. Under such conditions cyanosis is ordinarily absent.

The mechanism which brings about the loss of alkali into the urine has remained obscure, but two explanations have been suggested. Marshall, Cutting, and Emerson propose the following: "It is possible that this (alkaline urine) may be due to lack of reabsorption of bicarbonate and base from the glomerular filtrate, the reabsorption of a large amount of the filtered sulfanilamide interfering with that of the bicarbonate." However, they did not present experimental evidence bearing on this point directly. On the other hand, Hartmann, Perley, and Barnett have, on the basis of clinical observations, taken the view that sulfanilamide exerts its influence primarily on the respiratory mechanism, causing hyperpnea with resultant blowing off of carbon dioxide. They assume this to be followed in sequence by: (1) an increase in blood pH, and (2) a compensatory excretion of alkali by the kidneys. They, therefore, feel that the disturbance in acid-base balance should be properly regarded as a "carbon dioxide deficit type of alkalosis." This statement appears to have created some confusion, since they have also raised the question whether routine alkali administration in conjunction with sulfanilamide is "not only not indicated but definitely undesirable under certain circumstances."

*From the Research Laboratories, Winthrop Chemical Company.
Received for publication, April 15, 1940.

In view of the questions raised by Hartmann, Perley, and Barnett, it has seemed desirable to present further evidence bearing on the effect of sulfanilamide on acid-base balance, and, if possible, to demonstrate which of the suggested explanations of the disturbance is correct.

Fig. 1.—Loss of carbon dioxide combining power of plasma caused by sulfanilamide (prontylin) restored by the administration of sodium bicarbonate.

EXPERIMENTAL

I. Demonstration that sulfanilamide acidosis is relieved by alkali.—Five adult dogs were used as subjects. During a preliminary control period of five days the carbon dioxide combining power was determined daily until a normal value was established. Medication consisting of 0.5 Gm. of sulfanilamide per kilogram of body weight was then given in a milk suspension by stomach tube (in three equal doses at eight-hour intervals) daily. The carbon dioxide combining power was determined at the same hour each day until it appeared that no further decrease would occur, then the medication was supplemented with the amounts of sodium bicarbonate indicated in the figure (0.3 to 0.5 Gm. per kilogram per day, in three doses) until the original carbon dioxide combining power was restored. The results of this medication sequence are shown in Fig. 1.

Comment. The median normal carbon dioxide combining power for the group of animals was 51 to 52 volumes per cent. The administration of 0.5 Gm. of sulfanilamide per kilogram per day reduced the carbon dioxide combining power to a median value of 45 volumes per cent, after which no further decrease was noted. The administration of 0.5 Gm. of sodium bicarbonate per kilogram per day rapidly restored this value to 52 volumes per cent or more, but dosages

of alkali ranging (in separate experiments) from 0.1 to 0.3 Gm. per kilogram per day were not sufficient to bring about complete recovery.

II. *Demonstration that sulfanilamide acidosis is prevented by the administration of the proper amount of alkali.* A group of five dogs, including four from the previous experiment, was studied in the same manner as before to determine the normal carbon dioxide combining power. When this value was established, the animals were given 0.5 Gm. of sulfanilamide and 0.1 Gm. of magnesium oxide per kilogram of body weight per day as a single dose. The plasma carbon dioxide combining power was determined daily on a blood sample taken just before medication. This treatment was continued for ten days, and the results are shown in Fig. 2.

Fig. 2.—Simultaneous administration of sulfanilamide (prontylin) and magnesium oxide. No loss of carbon dioxide combining power results.

Comment. The data represented graphically in Fig. 2 indicate that the normal carbon dioxide combining power for this group of animals is again between 50 and 55 volumes per cent. This value remained practically unchanged during the period of medication, showing that the amounts of alkali and drug given are approximately equivalent physiologically, at least in the dog, and under the conditions of this test.

III. *Demonstration of the order of the changes in the various acid-base factors following sulfanilamide.* A female dog was trained to lie quietly unrestrained on a padded table for long periods of time, was accustomed to retain a urethral catheter and stomach tube, and to permit blood sampling. Respiratory rates and volumes were recorded by means of a pneumograph adjusted to the thorax and connected with a recording tambour, the excursions of which were recorded graphically on a smoked drum. After a satisfactory control period, medication consisting of 0.6 Gm. of sulfanilamide per kilogram of body weight suspended in milk was given by stomach tube (the tube was then removed). Blood samples were taken every thirty minutes and urine samples every fifteen

minutes up to three hours after medication, after which they were taken less frequently. The pH of each sample was immediately taken by means of the glass electrode, the blood determination usually being complete within forty-five seconds after taking the sample, or as soon as a constant reading could be obtained. The urine sample was kept under oil until the blood sample was finished. Respiratory exchange was calculated in arbitrary units; i.e., the rate of

Fig. 3.—Changes in the various acid-base factors following sulfanilamide medication. A, Respiratory exchange is given in terms of per cent of the value recorded during the period preceding medication. B, Figures given for sulfanilamide medication are medians obtained from three separate experiments. C, Figures given for sham medication are averages obtained from two separate experiments.

of alkali ranging (in separate experiments) from 0.1 to 0.3 Gm. per kilogram per day were not sufficient to bring about complete recovery.

II. *Demonstration that sulfanilamide acidosis is prevented by the administration of the proper amount of alkali.* A group of five dogs, including four from the previous experiment, was studied in the same manner as before to determine the normal carbon dioxide combining power. When this value was established, the animals were given 0.5 Gm. of sulfanilamide and 0.1 Gm. of magnesium oxide per kilogram of body weight per day as a single dose. The plasma carbon dioxide combining power was determined daily on a blood sample taken just before medication. This treatment was continued for ten days, and the results are shown in Fig. 2.

Fig. 2.—Simultaneous administration of sulfanilamide (prontylin) and magnesium oxide. No loss of carbon dioxide combining power results.

Comment. The data represented graphically in Fig. 2 indicate that the normal carbon dioxide combining power for this group of animals is again between 50 and 55 volumes per cent. This value remained practically unchanged during the period of medication, showing that the amounts of alkali and drug given are approximately equivalent physiologically, at least in the dog, and under the conditions of this test.

III. *Demonstration of the order of the changes in the various acid-base factors following sulfanilamide.* A female dog was trained to lie quietly unrestrained on a padded table for long periods of time, was accustomed to retain a urethral catheter and stomach tube, and to permit blood sampling. Respiratory rates and volumes were recorded by means of a pneumograph adjusted to the thorax and connected with a recording tambour, the excursions of which were recorded graphically on a smoked drum. After a satisfactory control period, medication consisting of 0.6 Gm. of sulfanilamide per kilogram of body weight suspended in milk was given by stomach tube (the tube was then removed). Blood samples were taken every thirty minutes and urine samples every fifteen

have been expected if the explanation proposed by Hartmann, Perley, and Barnett were correct. In the third place, we have observed in control experiments hyperpnea and increased blood pH without any change in the pH of the urine. Finally, the blood pH after sulfanilamide tends to *fall* slightly, and to rise later, but only after a respiratory acceleration becomes evident.*

CONCLUSIONS

1. Sulfanilamide causes a disturbance in acid-base balance characterized by loss of alkali from the blood into the urine. This probably has its origin in some type of interference with the reabsorption of bicarbonates from the glomerular filtrate. The phenomenon is, therefore, most accurately designated as a primary alkali deficit due to alkali loss.
2. The alkali deficit which occurs in dogs medicated with sulfanilamide may be compensated by giving alkalis in about the amount of 100 mg. of magnesium oxide or 500 mg. of sodium bicarbonate per 500 mg. of sulfanilamide.

33 RIVERSIDE AVENUE

*After this paper was submitted for publication it came to our attention that Hartmann has reiterated these same views with new experimental subjects without, however, using any new experimental approach. Our opinion that his views are incorrect remains unchanged. That such is the case is well illustrated by the chart on page 951. Here the urine pH rises immediately after medication, while the serum pH rises slowly (and insignificantly, since within normal limits) over a period of several days. In other words, the "effect" precedes the "cause." The ammonium chloride medication followed by sulfanilamide seems to have little bearing on the question. It is hardly to be expected that during, or immediately after, an overwhelming acidifying dose (enough to neutralize several times all the bicarbonate in the blood plasma) the kidney would begin to excrete bicarbonates. Any bicarbonate escaping reabsorption at this time would naturally be neutralized in the very acid urine.

THE CAPACITY OF THE KIDNEY TO CONCENTRATE URINE IN ACUTE GLOMERULONEPHRITIS*

RAYMOND GREGORY, PH.D., M.D., GALVESTON, TEXAS

IT IS the purpose of this paper to call attention to the infrequency with which attention is paid to the power of the kidney to concentrate the urine in acute glomerulonephritis and to point out what appears to be an error in most of the discussions of this subject. I will review the literature on the subject and report additional cases of acute glomerulonephritis with impairment of ability to concentrate the urine. My previous experience with a number of cases of acute glomerulonephritis has been at variance with the statements in the usual sources concerning the capacity of the kidney to concentrate urine in acute glomerulonephritis. Unless stated to the contrary, acute glomerulonephritis is used here as a designation for the diffuse variety of this disease.

In the important review of the subject of nephritis by Van Slyke and others,¹ I have found no mention of the capacity of the kidney to concentrate when affected by acute glomerulonephritis. Nor do Peters and Van Slyke² discuss this function of the kidney in acute glomerulonephritis. Inasmuch as both papers adequately cover the concentration of the urine by the kidney in chronic glomerulonephritis, one might infer that they do not consider that there is any significant change in this function of the kidney in acute glomerulonephritis.

In this paper the values for the specific gravity of the urine as a criterion of the kidney's concentrating power are based on the work of Addis and Shevky,³ Lashmet and Newburgh,⁴ and Lundsgaard⁵ who used a slightly modified Volhard test. Their results vary slightly, but all are in agreement that with proper technique the kidney should concentrate to a specific gravity of at least 1.025. Addis and Shevky found 95 per cent of normal individuals could concentrate above 1.028, and 100 per cent of normal individuals could concentrate above 1.026.

CASE REPORTS

CASE 1.—W. K., a 17-year-old colored school boy, was admitted to the hospital on September 25, 1938. For many months he had prolonged head colds with severe frontal headaches suggestive of sinusitis. The present illness developed insidiously and began with swelling of the face, malaise, and anorexia one month before admission. One week after onset there was swelling of the abdomen, and finally slight swelling of the feet. He was not aware that he had bloody or smoky urine, or any decrease in urine output. He had increasing edema of the face and swelling of the abdomen and progressive weakness.

Examination showed marked edema of face and trunk, and slight edema of the extremities. The edema was of the hard, brawny type and pitted with difficulty. Subsidizing bilateral otitis media was present; the right ocular fundus showed papilledema, several

*From the Department of Medicine, Howard University Medical School and the Medical Service, Freedmen's Hospital, Washington, D. C.
Received for publication, May 31, 1940.

small hemorrhages above the disk, arteries of smaller than normal caliber but no exudate. There was marked pnpilledema on the left. The heart was enlarged to the left, the total transverse diameter being 15 cm., and that of the chest 26 cm. A diastolic murmur was heard along the left border of the sternum and the blood pressure was systolic 158 and diastolic 70. Slight jugular distention, edema of the abdominal wall, slight shifting dullness in the abdomen and slight edema of extremities were present. The spleen descended 2 to 3 cm. below the left costal margin on deep inspiration.

Eight uric examinations were made. All of them showed 2 plus to 4 plus albumin and were acid in reaction. The specific gravity of seven specimens was 1.012, one was 1.015. Only one specimen was positive for blood. Red blood cells were 2,530,000, hemoglobin 34 per cent, white blood cells 13,000, polymorphonuclear cells 88 per cent, lymphocytes 12 per cent. Blood serology was negative.

The patient had fever during his entire stay in the hospital. Both ears drained during most of his hospital course. After one negative culture the blood culture repeatedly showed hemolytic streptococci. The diastolic basal murmur became progressively louder and was associated with a diastolic thrill for the last few days of life. Total blood plasma protein was 7.8 per cent, albumin 3 per cent, and globulins 4.8 per cent. A roentgenogram of the chest showed the total transverse cardiac diameter to be 16 cm., and the chest diameter to be 27.5 cm. On admission the nonprotein nitrogen was 22 mg. per cent, and creatinine 1.7 mg. per cent (frequently found as a normal value in this laboratory). There was a progressive increase in nitrogen retention, which was 85.7 mg. per cent of nonprotein nitrogen, 7.5 mg. per cent of creatinine, and 19 volumes per cent of carbon dioxide combining power the day before death.

The fluid intake was 300 c.c. and 600 c.c. the first and second hospital days, respectively. The output of urine was 300 c.c. and 360 c.c., respectively, the first two days in the hospital. The first twenty-four hours he lost one-half pound, or roughly 250 Gm. During the first week he lost an average of 374 Gm. daily. It is believed that this loss of weight was not all due to fluid loss because of his fever and the extremely small food intake. The specific gravity of the urine was 1.012 on each of the first two days when the output was much diminished. He died on October 18, 1939, twenty-three days after admission.

The clinical diagnoses were acute diffuse glomerulonephritis, acute bacterial endocarditis due to a hemolytic streptococcus on the aortic or pulmonary valves, aortic or pulmonary insufficiency, bilateral otitis media, and hemolytic streptococcal septicemia.

Dr. R. S. Jason, of the Pathology Department, performed a necropsy seven hours after death. The kidneys were enlarged, the combined weights being 705 Gm. The capsules stripped with ease, showing numerous petechial hemorrhages in the cortex. The cut surfaces bulged markedly, the pyramids were dark colored. Microscopic examination of the kidneys showed capsular proliferation, many glomeruli were avascular and showed proliferation of the endothelial cells. Tubular degeneration was marked. An anatomic diagnosis was made of acute thrombo-ulcerative endocarditis of the pulmonary valve; septic emboli to both lungs; diffuse proliferative capsular glomerulonephritis; degeneration of parenchymatous organs and acute splenic tumor; slight dilatation of heart; passive congestion of lungs, liver, spleen, and kidneys; dependent edema; slight osteitis and hydropericardium; and bilateral suppurative otitis media. Cultures from the spleen showed hemolytic *B. coli*; from the lung, *B. coli* and hemolytic streptococci.

Comment.—No concentration tests were done as such. I believe it to be important, however, that the specific gravity of the urine was 1.012 on two days when the output was 300 c.c. and 360 c.c., respectively. That diuresis was likely not a factor in the low specific gravities recorded is further shown by the weight loss of this patient. The first day he lost one-half pound, roughly 250 Gm. During the first week he lost five and one-half pounds, an average of approximately 374 Gm. per day. This was probably not all due to fluid loss because he ate very little, in spite of the fever. On the days when the specific

gravity was 1.012 and the urinary output was very low, the urine contained three-plus albumin. The specific gravity corrected for the albumin would likely have been 1.011 or 1.010.

CASE 2.—H. A., a 51-year-old colored male janitor, was admitted to the hospital on March 29, 1939, and was discharged improved on June 14, 1939. His complaints were shortness of breath, swelling of the feet, legs, and abdomen, and weakness. In February, 1939, he had a disease characterized by fever, generalized aches and pains, and diagnosed as "grippe" by a physician. About February 20 he returned to work but became progressively weaker. Shortness of breath and swelling of his abdomen gradually developed. Swelling of the feet and of the face occurred a few days before admission.

Examination showed him to be pale. He could lie flat without respiratory embarrassment. His heart was of normal size, his mechanism was normal, and his blood pressure was systolic 120 and diastolic 86. Edema of the abdominal wall, especially of the flanks, and two-plus pitting edema of the legs were noted. The fundi oculi were normal.

The urine was cloudy, acid, had a specific gravity of 1.014, and contained three-plus albumin. It was otherwise normal. The blood had red cells 4,570,000, hemoglobin 72 per cent, white cells 13,350, normal differential. Hinton and Eagle precipitation tests were negative.

During the patient's entire stay in the hospital he had no fever and a steady though slow improvement. Weight nineteen days after admission was 180 pounds; two days before discharge, 163 pounds. The weight on admission was probably greater than 183. More than twenty blood pressure recordings were systolic 110 to 120 and diastolic 70 to 80. On March 30, 1939, the venous pressure was 8 cm. of blood. On April 4, 1939, 1,300 c.c. of chyliform fluid was withdrawn from the abdomen, the specific gravity of which was 1.018. On April 12, 1939, the total blood plasma proteins were 4.7 Gm., albumin 2.3, and globulin 2.4. In spite of a four-plus albuminuria the maximal concentration of the urine was 1.015 sixteen hours after abstaining from food and drink. A urea clearance of 9 per cent of maximal clearance and a blood nonprotein nitrogen of 91 mg. per cent were found. On May 6, 1939, the red blood cell count was 2,850,000 and hemoglobin was 40 per cent. On May 12, 1939, the red blood cell count was 3,050,000. On May 18, 1939, urea clearance was 13 per cent of maximal normal; total proteins 4.9, albumin 1.5, globulin 3.4, and the blood nonprotein nitrogen 53.2 mg. per cent. On May 25, 1939, the twenty-four-hour specimen of urine measured 1,100 c.c. and contained 17 Gm. of protein. On June 5, 1939, the nonprotein nitrogen was 31.6 mg. per cent, creatinine 3.0 mg. per cent (normal values in this laboratory often 2). On June 9, 1939, total protein was 6.0 Gm., albumin 3.5, globulin 2.5, urea clearance 15 per cent of the standard clearance.

Clinical diagnoses: Acute glomerulonephritis, ascites, and uremia.

Comment.—Twelve urine specimens contained three-plus to four-plus albumin for the first six weeks in the hospital. Red blood cells were found in the urine only infrequently. Of fifteen urine examinations twelve had a specific gravity of 1.017 or below (1.013 to 1.017); two were 1.018; one was 1.020 one month after admission. In spite of marked edema, ascites, and albuminuria on admission, the specific gravity of the urine was 1.014. On April 20, 1939, in spite of a four-plus albuminuria, the maximal concentration of the urine was 1.018 sixteen to seventeen hours after no food or fluids. It appears from the above data that the impairment of the tubular function was not as extreme as that of the glomerular function. But if the correction is made for the albumin content of the urine, the specific gravity of the urine indicates a greater degree of tubular damage. It is known⁶ that urines which contain a large amount of protein have more than 0.5 per cent. One quantitative estimation of this patient's urine indicated that he had 1.5 per cent. It seems fair.

therefore, to assume that the urines which had three- to four-plus albumin contained approximately 1 per cent albumin. A correction⁷ for the amount of albumin would result in a maximal concentration of 1.015 instead of 1.018.

CASE 3.—O. T., a colored school girl, 15 years of age, was admitted to the hospital on December 6, 1938, with the complaint that four weeks before she was admitted her illness had begun with severe frontal headaches and drowsiness associated with swelling of the face, particularly the eyelids, and feet. The edema subsided during the day and recurred during the night. Seven days before admission visual impairment became so marked that she consulted an ophthalmologist. She gave no history of a previous respiratory or any other type of infection for many months prior to onset of the illness. The urine assumed a darker color during the present illness, but she had not been aware of bloody or smoky urine or any diminished volume. Urinary frequency was four times daily and once at night. She said her face was less swollen than at the beginning of her illness.

Examination showed the face and lids edematous. The blood pressure was systolic 115 and diastolic 80, the heart and lungs were normal, the tonsillar lymph nodes were enlarged, the tonsils were absent, the spleen was not felt, the abdomen was normal. The patient was in a good nutritional state and reflexes were normal. Fundus examination showed marked bilateral papilledema, numerous splinter hemorrhages in both eyes, veins engorged, very slight unevenness of caliber of arteries, a few cotton wool exudates close to the disks, macular areas normal, and two flame-shaped hemorrhages a disk's diameter above right disk.

The urine was acid and cloudy and had a specific gravity of 1.020; it gave a three-plus albumin reaction, and was negative for sugar, acetone, and bile. The sediment showed many long granular and cellular casts, numerous red blood cells, and the benzidine test on the sediment was strongly positive for blood. During the next two months fifteen examinations of the urine were made. A three-plus albuminuria was present on all but two occasions, when it was two plus. Microscopic and/or chemical tests for blood were positive in all but three specimens. Granular casts were found seven times in the fifteen examinations.

The blood on December 8, 1938, showed red blood cells 3.48 million, hemoglobin 54 per cent, white blood cells 4,050, essentially normal differential. On January 3, 1939, red blood cells showed 2.4 million, hemoglobin 28 per cent; the reticulocyte count on January 16 was 4.2 per cent. The red blood cell counts remained from two to three million and the hemoglobin from 28 to 52 per cent. The white blood cell count was low for the first six weeks in the hospital when it went to 11,400. There was a constant leucocytosis from 18,450 on January 20 to 27,800 on January 23 and 22,550 on February 1. On and after February 20 the polymorphonuclear cells were 83 per cent or greater. On December 7, 1938, one day after admission, nonprotein nitrogen was 54.5 mg. per cent, creatinine was 3.0 mg. per cent, carbon dioxide combining power was 53 volumes per cent; on December 12 nonprotein nitrogen was 46 mg. per cent, creatinine was 1.9 mg. per cent; on December 19 nonprotein nitrogen was 28 mg. per cent, and creatinine was 1.4 mg. per cent.

The patient had fever during her entire stay in the hospital; on several occasions her temperature was 104° and 105° F. On December 11, 1938, she was clinically improved, the edema was rapidly disappearing, and she was mentally more alert; the following day her blood pressure was systolic 114 and diastolic 78. Physical examination revealed a productive cough but normal lungs. On December 15, 1938, papilledema decreased, only one flame shaped hemorrhage remained in the right eye; the exudates previously seen had disappeared. Three days later eye grounds were essentially the same. She was given a transfusion of 400 c.c. of citrated blood on January 4, 1939. Two days later the specific gravity of her urine was 1.012; on January 8 the specific gravity of the urine was 1.012.

There were signs of fluid in left chest on January 21, 1939; pericardial friction rub was heard on January 23. The patient was having pain over the precordium, and both the right and left sides of her heart were considered enlarged. Tubular breathing was heard over the left base posteriorly. The question whether this was due to pericardial effusion or pleural or pneumonic disease was raised, but no conclusive decision was reached.

On January 30 two hemorrhages and exudate and papilledema were seen in the left fundus; on January 31 the Rumpel-Leede capillary fragility test was positive. The blood pressure was systolic 140 and diastolic 98. Nonprotein nitrogen was 160 mg. per cent, creatinine was 3.0 mg. per cent, total blood plasma proteins were 6.25, albumin was 2.10, and globulin was 4.15; uremic frost was observed along hair margins. On February 1 total protein was 6.25 Gm. per cent, albumin 2.10 Gm. per cent, globulin 4.15 Gm. per cent, nonprotein nitrogen 160 mg. per cent, creatinine 3.0 mg. per cent; the following day nonprotein nitrogen was 210 mg. per cent and creatinine 3.5 mg. per cent.

Concentration Tests.—(All water and food were withheld fourteen to sixteen hours and the bladder was emptied one to two times before the specimen was obtained for specific gravity estimation.) On December 7, 1938 (the day after admission, four weeks after onset), the specific gravity was 1.019, albumin was three plus; on December 15, specific gravity 1.018, albumin three plus; on December 23, specific gravity 1.017, albumin three plus; January 5, 1939, specific gravity 1.010, albumin two plus; January 8, specific gravity 1.016; January 9, specific gravity 1.012, 90 c.c.; January 10, specific gravity 1.006, 90 c.c.; January 12, specific gravity 1.012, 120 c.c.; January 13, specific gravity 1.012, 150 c.c.; January 14, specific gravity 1.010, 210 c.c.; January 15, specific gravity 1.010, 150 c.c.; January 16, specific gravity 1.007, 180 c.c.

The course grew progressively worse and the patient died February 4, 1939, on the sixty-second hospital day. Permission for necropsy was not obtained.

Clinical diagnoses: Acute glomerulonephritis terminating in uremia, septicemia of undetermined etiology, uremic pericarditis with effusion.

Comment.—This patient probably had impairment of concentrating capacity when she was admitted to the hospital dehydrated, edematous, and with a urine specific gravity of 1.020 and a three-plus albuminuria. There was a gradual decrease in this function until the concentrating capacity was fixed at 1.010 to 1.012 after January 9, 1939. The necessity for making corrections for the albumin content of the urine in specific gravity estimations in concentration tests is again emphasized.

CASE 4.—J. R., a 29-year-old colored clerk, was admitted to the hospital on October 10, 1938, complaining of shortness of breath and a bad cough. The present illness began three weeks before admission with a "head and chest cold" after he had become thoroughly soaked in a rainstorm. He had chilly sensations and fever from the onset of his illness. Several days before admission he developed extreme shortness of breath, edema of lower extremities, headaches, and dizzy spells. Urinary frequency was five to six times in the day and three to four times during the night. Two months before admission he had had gonorrhea which had been treated successfully by a physician.

He exhibited a great amount of unproductive coughing. Examination showed orthopnea. The conjunctivae were markedly blood shot; face and eyelids were "puffy." The fundi oculi showed no pathology. The jugular veins were slightly distended and there were congestive râles in the lung bases. The heart was enlarged to the left anterior axillary line in the fifth interspace. The apical thrust was not forceful. There was a gallop rhythm and pulsus alternans, the heart rate was 140, and the blood pressure was systolic 196 and diastolic 160. There was a small amount of fluid in the abdomen, the liver was tender and extended 4 cm. below the right costal margin. There was a grade two to three edema of both lower extremities up to the knees and slight tenderness in the right costovertebral angle.

The urine on admission showed a specific gravity of 1.026 and contained four-plus albuminuria. It was cloudy and contained numerous red blood cells per low-power field and occasional granular casts. The blood showed red blood cells 4.2 million, hemoglobin 85 per cent, white blood cells 8,300, neutrophils 80 per cent, lymphocytes 19 per cent, and basophiles 1 per cent.

He was given absolute bed rest, digitalis, and sedatives; fluid and salt were restricted. His temperature was within normal limits with the exception of two dif-

ferent days when it reached 100.4° F. rectally. Blood pressure was systolic 196 and diastolic 160 on admission and remained elevated during his stay in the hospital. The weight on admission was 158 pounds; one week later, October 17, 144 pounds; October 24, 139; October 31, 134; November 7, 131; November 14, 129. On October 11 nonprotein nitrogen of the blood was 100 mg. per cent, creatinine 3.0 mg. per cent. On October 15 nonprotein nitrogen was 50 mg. per cent, creatinine 2.3 mg. per cent, carbon dioxide combining power 53 volumes per cent; October 24, nonprotein nitrogen 40 mg. per cent, creatinine 1.3 mg. per cent.

The urine was acid on October 11, had a specific gravity of 1.022, two-plus albumin, six red blood cells per high-power field, and an occasional granular cast. On October 14 the urine was pale yellow, acid, had a specific gravity of 1.009, and three-plus albumin, white blood cells 3 to 4, no red blood cells, one to two granular and hyalin casts; October 15, urine pale, neutral, specific gravity 1.010, two-plus albumin. He developed signs of a pulmonary infarct in the right lower lobe. On October 22 the signs of congestive failure and pulsus alternans had disappeared; urine acid, specific gravity 1.018, two-plus albumin; October 28, uriae acid, specific gravity 1.010, albumin one plus, few red blood cells, and three granular casts per high-power field; October 31, urine yellow, acid, specific gravity 1.017. Hinton and Eagle precipitation tests were negative. He was discharged on November 14, 1938, as improved.

Clinical diagnoses: Acute glomerulonephritis, cardiac dilatation, congestive heart failure, and pulmonary infarct.

Comment.—This man unquestionably had congestive heart failure. The clinical picture otherwise was characteristic of acute glomerulonephritis. I believe that the nonprotein nitrogen value of 100 mg. per cent was too high to be explained on the basis of congestive heart failure, although this probably contributed to the renal failure. The number of red blood cells was also much higher than the few one commonly sees in the urine due to passive congestion of the kidneys. I have concluded that the primary disease was acute glomerulonephritis and that the heart failure was that which is not uncommonly associated with acute glomerulonephritis.

My justification for including this case in this paper is that the urinary specific gravity on admission was 1.026 with a four-plus albuminuria and marked congestive heart failure, both of which factors raise the specific gravity of the urine. It should be noted also that the specific gravity of the urine for the first week after the first specimens gradually reached the level of 1.010. It may be argued that this was in part due to diuresis.

My principal purpose in including this case in this report is to emphasize that there may be nitrogen retention in acute glomerulonephritis with less decrease in the tubular function of concentration than one usually sees in chronic glomerulonephritis.

REVIEW OF LITERATURE

It is stated in commonly consulted sources⁹⁻¹⁹ that the specific gravity of the urine in acute glomerulonephritis is normal or even high. Some of the statements, however, are conflicting. Boyd,^{12, 19} for example, says that acute nephritis is characterized by a urine of high specific gravity and a low urea content. It appears to me that these two statements are incompatible in view of the fact that urea is one of the substances which is normally concentrated to a greater degree than any other substance in the urine. Unless glomerulonephritis is associated with a decreased formation of urea, or there is a unique interference with the capacity of the kidney to concentrate urea alone, neither

of which is true so far as I am aware, it would seem that it is impossible for a high specific gravity of urine to exist with a low urea content. The statement relative to the low urea content of the urine implies either specific impairment of the glomerular filtration of urea, increased tubular absorption of urea, or some impairment of the tubular function of concentration in general. The latter seems a more logical explanation of a low urine content of urea.

The statements in Best and Taylor¹³ also are ambiguous. Referring to the pathology of acute glomerulonephritis they say, "Such a severe reaction must of course, if widespread, cause a high degree of renal insufficiency. The following are among the chief features which may appear: retention in the blood of non-protein nitrogenous products; edema;; and the passage of a small quantity of urine with a high specific gravity." These authors¹⁴ then proceed to define renal insufficiency as a "reduced capacity of the kidney to carry out its functions;" and include a diminished concentrating power as an invariable accompaniment of renal insufficiency.

Bell²⁰ also appears ambiguous or inconsistent in his discussion of the concentrating capacity of the kidney in acute glomerulonephritis. For example, on page 497 he states, "In this publication clinical acute nephritis includes all cases of acute renal disease that exhibit a definite impairment of renal function indicated by retention of nitrogenous products, decreased ability to excrete P.S.P., *inability to form a concentrated urine*, loss of large amounts of protein in the urine, bleeding from the parenchyma of the kidney and severe oliguria and anuria." While on page 523 he says, "The total glomerular filtrate is decreased in amount in severe cases and it is distributed through more tubules than under normal conditions, in which only about one-third of the nephrons are active at any one time. The decrease of glomerular filtrate tends to cause retention of metabolites. The distribution of filtrate through a larger number of tubules where it is exposed to a greater reabsorption tends to produce a concentrated urine."

I offer the following criticism of this concept. In the first place, Bell includes in his definition of acute nephritis an inability to form a concentrated urine. He then proceeds to show why the severe forms of acute glomerulonephritis are able to concentrate their urine. In the second place, this concept appears to be based on two assumptions which may or may not be true. At any rate I know of no proof that they are true. Bell appears to assume that all the glomeruli in acute nephritis are open all the time and never shut down. If this really were the case, it would appear logical to believe that the constant filtration through the glomeruli would not allow the urine to remain in the tubules sufficiently long to concentrate it, inasmuch as it seems likely that the greatest amount of concentration may occur in the tubules when the glomerular capillaries are not open. This concept also fails to take into consideration that all glomeruli and all capillaries of each glomerular tuft are not normally open at any one time. This concept of Bell's further assumes that the tubules associated with these glomeruli are functioning normally, in spite of his statement that in severe cases the glomeruli are practically bloodless from intracapillary and extracapillary exudation and proliferation.

If the latter is so, and it is a common teaching of pathologists, it appears to me that it is not in accord with the facts to assume that the tubules of these nearly bloodless glomeruli can function normally when they too are practically deprived of their blood supply by the glomerular pathology. This statement is based on the work of Hou-Jensen²¹ and Clara²² who have shown that at least 97 per cent of all the arterioles of the medulla (tubules) of the kidney arise from the vasa efferentia.

On the basis of the work of Alving and Van Slyke²³ who showed that concentrating capacity may return many months after return of urea clearance, it seems logical to me to believe that the disturbed tubular function in glomerulonephritis may be due not only to a diminished blood supply from bloodless glomeruli, but also to a specific effect of the toxic agent on the capillaries of the tubule itself.

As a further example of the widespread and firm belief that the kidney in acute nephritis retains its capacity to concentrate the urine well, Albright²⁴ states, in the discussion of a case, that the differential diagnosis rests between acute and chronic nephritis; but that decision against acute nephritis was made because, among other things, the patient failed to concentrate the urine above 1.014 maximum. The case was shown at autopsy to be one of acute glomerulonephritis.

In contradistinction to the above case, which showed a nitrogen retention and a low capacity to concentrate, may be mentioned another case from the same source²⁵ (Case 12, Table I). The onset of illness was three weeks before admission, with marked edema of the extremities, genitals, and face; blood pressure was systolic 150 and diastolic 110; albumin and casts were present in the urine; nonprotein nitrogen was 38 mg. per cent, and dilution and concentration test was 1.002 to 1.032. The tubular function was normal and there was no gross evidence of glomerular failure as observed by the normal blood nitrogen. In other words, it appears that if the capillaries of the glomeruli are sufficiently open to prevent nitrogen retention, the tubules get enough blood to allow them to concentrate the urine normally. And if the glomerular capillaries are sufficiently damaged to cause nitrogen retention, the tubules are sufficiently disturbed functionally to result in impaired concentration.

In spite of Christian and O'Hare's¹⁵ statement regarding the high specific gravity of the urine in acute nephritis, their reported cases would appear to be out of accord with their statement. The interpretation, however, is difficult in view of the fact that we do not know the method by which the urine was collected. For example, Case 1 had fourteen specimens examined over a three-month period. Only three of these are above specific gravity 1.020, and ten specimens range from specific gravity 1.013 to 1.019. One specimen was 519 c.c. for twenty-four hours and had a specific gravity of 1.015. Case 3 had nineteen urine specimens examined over a period of fifty-two days, with a specific gravity ranging from 1.010 to 1.017. Most of these were twenty-four-hour specimens. This patient was followed for six months after this, the specific gravity varying between 1.011 and 1.022. Eighteen months after onset of illness the specific gravity was 1.025. Case 5 had twelve specimens examined, with the specific gravity ranging from

TABLE I

SUMMARY OF TWENTY-TWO CASES OF ACUTE GLOMERULONEPHRITIS FROM THE LITERATURE AND FOUR ADDITIONAL CASES WHICH SHOW IMPAIRED CAPACITY TO CONCENTRATE THE URINE

CASE NO.	AGE SEX	PRECEDING INFECTION	INTERVAL AFTER ONSET OF OBSERVATION	BLOOD PRESSURE	URINE	CONCENTRATION TEST—MAXIMUM	UREA CLEARANCE	BLOOD NITROGEN	EDEMA	OLIGURIA	AUTHOR
1	45 Male	Cellulitis of hand, lymphangitis of arm	At once	185/115	Blood, W.B.C., albumin, casts	1.020 (Addis)	Not done	Blood urea 98 mg. %	Marked	Positive	Addis and Oliver
2	24 Male	Scarlet fever	3 weeks after onset of symptoms	180/105	R.B.C., W.B.C., albumin, casts	1.018 (Addis)	Not done	Blood urea 189 mg. %	Marked	Positive	Addis and Oliver
3	29 Male	Strept. hemolyticus septicemia	3 weeks. Dead 4 weeks after onset	118/50	R.B.C., W.B.C., albumin, casts	1.014 (Addis)	Not done	Blood urea 206 mg. %	Positive		Addis and Oliver
4			6 weeks after onset	170/55 110/65	Blood, albumin	1.001 to 1.010 1.001 to 1.024 (Vollhard)	39 c.c./min., 52% maximal normal	Blood urea 160 mg. %			Rehberg
5	31 Male	Cut finger, axillary abscess	3 weeks 6 weeks	150/100	Gran. and hyalin and cellular casts, albumin, 2 plus	Onset 3/12; 4/2: 1.012 to 1.020; 4/25: 1.017	Not done	Not mentioned	Marked		Longcope
6	26 Male	"Cold"	7 weeks	164/92	4 plus albumin	1.012 to 1.020	Not done	Not mentioned	Positive, feet		Longcope
7	48 Male	Not given	At onset	100/90	Hematuria	1.012 max.; two observations at 3 mo. interval 1.020	12% avg. normal; 80% after 3 mo.	Not given	2 plus		Alyng and Van Slyke

8	43 Male	Not given	1 month	158/90	Hematuria	1.011; still im- paired to 1.012 after 3 mo.	10% avg. nor- mal; normal after 3 mo.	Not given	Absent on admission	Alving and Van Slyke
9	11 Male	Not given	13 months		Hematuria	After 5 yr.; max. 1.018	Normal clear- ance for 5 yr.	Not given		Alving and Van Slyke
10	Male	Boil 3 weeks before admission	Uncertain	140/95	Blood, many R.B.C., W.B.C., albumin, casts	1.006 to 1.014	Not done. No P.S.P. in 1 hr.	N.P.N. 101 mg. %	Positive	Case reports, Mass. General Hospital
11			2 weeks before admission	150/110	R.B.C., W.B.C., albumin, casts	1.002 to 1.032	Not done	N.P.N. 38 mg. %	Marked ex- trimitics, puffiness, over eye- lids and face	Case reports, Mass. General Hospital
12	17 Male	Sore throat	8 days	Not given	Albumin, hematuria, marked	1.013 max.; 1.015 after 3 mo.	Creatinine clearance 14 c.c./min.; clearance had returned to 80 c.c. after 3 mo.	Blood urea 90 mg. %	Not given	Holten
13	19 Female	Erysipelas onset 1/17	3 weeks	Not given	Albumin, hematuria	2/9: 1.017; 2/16: 1.010; normal 6 mo.	Creatinine clearance filtration 9.5 c.c./min.; low 17 mo.	Blood urea 2/9: 140 mg. %; 2/16: 200 mg. %	Not given	Holten
14	5 Male	Scarlet fever	Immediately after onset			1.010 on admis- sion; normal after 41 days	Slightly impaired	Blood urea 90 mg. %		Holten

1.008 to 1.014. Eleven months after onset of illness, the specific gravity was 1.019; forty-two months after, it was 1.028. The last two specimens were single-voided specimens. In the absence of specific knowledge of the method of collecting the specimens, one cannot state too definitely that the figures are evidence of a diminished concentration capacity of the kidneys. It may be fairly assumed that there was some uniformity of collection of specimens, and the trend upward in specific gravity, with the passage of time, may possibly be interpreted as evidence of previous impairment of concentration.

Difficulty also arises in connection with Christian and O'Hare's cases in the matter of deciding to what extent diuresis may have been a factor in the low specific gravities reported. The fact, however, that Case 1 had urinary specific gravities of 1.012, 1.014, and 1.015, while at the lowest recorded weight of 58.2 kg., would indicate that diuresis was probably not the cause of the low specific gravity. In Case 3, the specific gravities of 1.010 and 1.014 were also on days when the lowest weight of 51.2 kg. was recorded. This fact appears to render diuresis an unlikely explanation for the low specific gravity. Diuresis was probably not the explanation of the low concentrations of the urine in Case 5, as evidenced by specific gravity of 1.008 and 1.011, with the highest weight of 62.8 kg. on admission, which fell in eighteen days to 52.8 kg., the lowest recorded; the urine, however, continued to show specific gravities of 1.009, 1.010, and 1.011 at the lowest weight recorded.

The report of Murphy, Grill, and Moxon²⁶ is also difficult to interpret accurately regarding the concentrating capacity of the kidney in acute glomerulonephritis. It is of suggestive importance, however, that in twenty patients who became chronic cases the second specific gravity recorded in each case (one to four months after the first) was lower than that on the first study. On the other hand, the specific gravity in ten patients who recovered, the second observation being one to four months after the first, the specific gravity at the second examination, with one exception, was higher than that of the first examination. It seems fair to assume some uniformity in the manner in which the first and second urines were collected in each instance.

I have been able to find but few instances in which the concentrating capacity of the kidney in acute glomerulonephritis has been studied by any of the concentration tests. Most of the reports on acute glomerulonephritis, therefore, are of little value to the purposes of this article. Yet in one year's time I have observed four cases of acute glomerulonephritis with impairment of concentration capacity on a relatively small medical service.

While the general sources cited indicate that the capacity of the kidney to concentrate is unimpaired in acute nephritis, most of the special works on the kidney do not agree with this viewpoint. I have found twenty-one cases of acute nephritis with such impairment found by ten different observers in the relatively recent literature. These cases are summarized in Table I, together with the four additional cases described here.

Addis and Oliver²⁷ reported three cases of acute glomerulonephritis with unquestioned impairment of concentration (Cases 1, 2, 3, Table I). Rehberg²⁸ studied six cases of acute glomerulonephritis from which he concluded that the tubular function may also be affected in this stage of the disease. He gives data

from only one case, however (Case 4, Table I). Longcope²⁹ studied nine cases of acute glomerulonephritis, but only two of these had studies directed at the power of the kidney to concentrate the urine; both of these showed impaired concentration (Cases 5 and 6). The Addis technique was observed in one of these and the volume of the twelve-hour night urine was found normal. The low specific gravity, therefore, was not due to diuresis.

Volhard and Fahr³⁰ state that the concentrating capacity is impaired in acute glomerulonephritis as follows: "The lower the specific gravity of the urine, with small amounts of urine, the greater the kidney damage"; and "In general, in the more severe forms of acute glomerulonephritis the rule is the concentrating capacity of the kidney suffers; and indeed the more so, the more intensively and extensively the glomeruli are diseased." They give very brief summaries of two cases which demonstrated this feature (Cases 19 and 20).

Although Volhard states in another place³¹ that the concentrating capacity of the kidney was only slightly or not at all disturbed in acute glomerulonephritis, the two cases which he cites had markedly impaired capacity to concentrate the urine (Cases 21 and 22).

Donath³² has reported three patients with acute glomerulonephritis who showed impaired concentrating capacity of the kidney (Cases 16, 17, 18). While in two patients there was very slight nitrogen retention and in one there was none, all three had impaired concentration at times when the blood nitrogen was normal. There was also impairment of the capacity to dilute the urine. Both types of impairment persisted after red blood cells, casts, and albumin disappeared.

Holten³³ studied 25 patients with acute glomerulonephritis with the Volhard-Strauss concentration technique and the creatinine clearance test of Holten and Rehberg.³⁴ In this group there were four instances (Cases 12 to 15) of either moderate or severe impairment of concentration, and two other instances of slight impairment. In all instances in which elevation of blood nonprotein nitrogen occurred, there was diminished capacity to form a concentrated urine. In one patient the filtration rate returned to normal before the concentration test. This was also shown by one of the patients of Alving and Van Slyke. The possible significance of this will be discussed in connection with the work of Alving and Van Slyke.

Holten³³ is well aware, of course, that the concentrating capacity of the kidney may be retained in acute glomerulonephritis, but states further that he has never seen it retained in patients with serious impairment of the filtration rate (below 10 c.c. per minute). He cites Volhard's explanation for the maintenance of the concentrating capacity of the kidney in acute nephritis, namely, that the tubules are able to excrete solids to a normal extent and the glomeruli are unable to excrete water.

Alving and Van Slyke²³ have shown results which are interesting and pertinent to the present paper in their comparative values of the urea clearance and concentration tests in Bright's disease. In three transitory cases of glomerulonephritis (hematuria, proteinuria, and initial edema left no doubt that each patient had an acute nephritis) both urea clearance tests and concentration tests

were normal throughout. They also had three cases (Cases 7, 8, 9) of acute glomerulonephritis which had impairment of both the urea clearance tests and concentration tests. Their fourth case had an original urea clearance of 12 per cent of the average normal and a maximal concentrating capacity of 1.012. Three months later the clearance test had risen to 80 per cent of average normal, but the concentration capacity by both the Addis-Shevky and Lashmet-Newburgh tests had risen only to from 1.019 to 1.020. Later this also returned to normal. Their fifth case also showed a marked lag in the return to normal of concentration capacity after the clearance had returned to normal. Three months after onset the urea clearance was normal, but the Addis test showed a maximal concentration of 1.012 which later returned to normal. Their seventh case did not have a return to the normal concentration capacity until five years after the urea clearance was normal.

Lyttle³⁵ calls attention to impairment of concentration in severe cases of acute nephritis, but does not give any cases to demonstrate it.

Goldring, Clarke, and Smith³⁶ showed that at low plasma levels of phenol red, about 94 per cent of the dye clearance is accomplished by tubular activity in the normal human kidney. On the basis of this work Goldring and Smith³⁷ have studied the glomerular and tubular functions of the kidney with inulin and phenol red clearance ratios in patients with various stages of glomerulonephritis. In general, they have found in the earlier stages of the disease that the phenol red-inulin clearance ratios tend to maintain the normal value, which is above 3.0. They have interpreted this as suggesting that injury of glomeruli and tubules progress in a parallel manner. In the more advanced cases, however, this ratio fell as low as 0.6, indicating almost complete loss of the capacity of the tubules to excrete the dye. In a few patients observed early in the acute stage of the disease, the phenol red-inulin ratio was 210 per cent of the average normal figure. In interpreting this they have suggested the possibility of dilatation of the efferent glomerular arteriole which would give a better blood supply to the tubules, and at the same time lower the effective filtration pressure in the glomeruli. They have also suggested that permeability of glomerular capillaries may be reduced without obstructing the blood flow.

COMMENTS

It may be readily understood from the anatomic relationships of the blood supply to the tubules, which is derived from the efferent glomerular arterioles, that the tubular function of concentration may suffer when the glomerular tufts are so damaged as to reduce the urea clearance to low levels. It is difficult to understand, however, why the tubular function may be impaired long after glomerular function has returned to normal. As a tentative explanation, I offer that the tubular capillaries in some instances are damaged to a great degree at the same time the glomerular tufts are damaged, the latter recovering more quickly.

It is certain that tubular function is impaired in acute glomerulonephritis. This is shown by the impaired capacity to concentrate urine, which is illustrated by the cases which have been summarized in Table I. It is further supported by the results of Goldring and Smith³⁷ which indicate that glomerular and tubular damage proceed in a parallel fashion.

On the basis of the reports by Holten³¹ and Alving and Van Slyke²³ of cases of acute glomerulonephritis which showed a return of urea or creatinine clearances to normal levels long before the return of the concentrating capacity, I have made the suggestion that tubular function may be impaired in acute glomerulonephritis not only because the tubular blood supply is disturbed in the diseased glomeruli, but also because the tubular capillaries themselves may possibly be the seat of specific pathology, or that specific damage to the tubular cells may account for it. The specific tubular capillary or cellular damage theory gains some support in the results of Goldring and Smith which showed in advanced cases of nephritis the reduction of the phenol red-inulin clearance ratios to such low levels as 0.6.

It may be seen from Table I that when there is sufficient glomerular damage in acute nephritis to cause nitrogen retention, there is sufficient tubular damage to interfere with the concentrating function of the kidney. I have found no exception in the literature to this. It has been emphasized that it is necessary to correct specific gravity values when the urine contains large amounts of protein.

It is my belief that impairment of concentrating capacity of the kidney will be found in most of the severe cases of acute glomerulonephritis if properly evaluated.

SUMMARY

The literature has been reviewed and twenty-two cases of acute glomerulonephritis with impaired capacity to concentrate the urine have been found and summarized in tabular form, together with four additional cases of acute glomerulonephritis which showed impairment of this function. Certain theoretical considerations have been discussed.

CONCLUSIONS

It is established that the capacity of the kidney to concentrate urine in acute glomerulonephritis may be impaired.

Most, if not all, cases with sufficient glomerular damage to cause blood nitrogen retention will show impaired ability to form a concentrated urine.

Nitrogen retention may occur in acute glomerulonephritis with less impairment of concentration than is usually observed with nitrogen retention in chronic glomerulonephritis.

The necessity for making corrections in the specific gravities of urines which contain large amounts of protein is emphasized.

The cause of impaired tubular function in acute glomerulonephritis is due, at least in part, to the interference with tubular blood supply produced by the proliferative and exudative processes in the glomeruli.

There is evidence that there may be a specific localized effect of the toxic agent of acute glomerulonephritis on the capillaries or cells of the tubules.

BLOOD CHEMISTRY DETERMINATIONS IN PERNICIOUS ANEMIA*

EVANS W. PERKINS, M.D., AND M. R. FREELAND, PH.D.
CHICAGO, ILL.

THE object of this paper is to report the blood chemistry determinations on 15 patients with pernicious anemia in a state of relapse. These were carried out with the hope that some alteration in the normal constituents of the body metabolism might be revealed which would aid in elucidating the obscure nature of this disease.

Minot and Murphy discovered that patients with pernicious anemia improved when given liver. Castle and his associates showed that patients with untreated pernicious anemia lacked in their gastric secretions an essential thermolabile substance termed the intrinsic factor. Sturgis and Isaacs later demonstrated the effectiveness of pig stomach in the treatment of pernicious anemia, and the similarity of this active principle to that found in normal human gastric juice. Both of these factors differ from the substance found in the liver, which is able to stimulate the bone marrow. It is assumed that the intrinsic factor found in the gastric juice combines with an extrinsic factor present in beef to form the active principle which is stored in the liver and is able to stimulate the bone marrow to normal activity. Dakin and West have demonstrated a substance in liver which is probably a dipeptide of β -hydroxyglutamic acid and L- γ -hydroxyproline which they believe to be the active principle in the liver. It was for some time believed that the extrinsic factor was the vitamin B₂ or G, which has been shown to be riboflavin. Mixtures of riboflavin and normal gastric juice, when administered to patients with untreated pernicious anemia, failed to elicit a reticulocyte response, and it is doubtful whether riboflavin is the extrinsic factor.

Even though we have a treatment for pernicious anemia, and have made progress in locating the site and the nature of the active principle, there is still much to be learned about the nature of the disease, and the active principle involved in its production. It is with this hope that we present the following data. All the determinations have been done in the laboratories of the Presbyterian Hospital of Chicago, and references to the methods used will be found in the bibliography.

Table 1 contains all the results on lipid metabolism we were able to obtain. We are cognizant of the fact that Peters and Van Slyke, in the chapter on lipoids, express the opinion that increased lipoids in the various types of anemia is merely an expression of a general reaction to loss of blood and hemoglobin from the circulating fluid. This reaction is said to consist of an increase

*From the Department of Internal Medicine, Rush Medical College, University of Chicago, and the Laboratories of the Presbyterian Hospital.

Received for publication, June 1, 1940.

of fat and fatty acids in the blood, and a simultaneous deficiency of the phospholipids and cholesterol. A summary of the results reveals the following:

1. Thirteen total lipid determinations done on 9 patients showed values twice that of normal or higher.

2. Sixteen total cholesterol determinations done on 12 patients demonstrated normal values in 6, moderately decreased in 9, and markedly decreased in 9. The distribution between the free and esterified form was essentially normal.

3. Lipoid phosphorus and lecithins were markedly diminished in 16 determinations done on 12 patients.

4. Of 11 fatty acid determinations done on 8 patients, 7 were much below minimal values, and 4 were below normal values.

13	30	0.98	4.8	21.5									

Table II shows the results of a smaller series of blood chemistry determinations done on 9 patients.

1. Amino acid determinations done on 6 patients showed normal values in 3, slightly elevated values in 2, and a value of 21 mg., which is nearly three times normal, in one.

2. Calcium and phosphorus determinations on 4 patients were normal as were two creatinine and three uric acid determinations.

3. Four nonprotein nitrogen determinations were done, 3 of which were normal and one slightly elevated. Two urea nitrogen determinations were normal, and the third, the same patient who showed the increase in the nonprotein nitrogen, showed also an increase in the urea nitrogen.

4. Two glucose determinations, as well as two carbon dioxide, and three sodium chloride determinations were normal.

TABLE III

CASE NO.	HB.	R.B.C.	W.B.C.	ROSE BENGAL* (%)		INORGANIC SULFUR	ETHEREAL SULFUR	TOTAL PROTEIN	ALBUMIN	GLOBULIN	A./G.
				10 MIN.	18 MIN.

6	55	2.08	5.6					8.41	4.63	3.73	1.22
9	68	2.80	8.7					5.5	3.76	1.74	2.16
10	28	1.28	3.2					6.27	4.15	1.18	1.95

*Normal values: 10 min., 55 per cent or less, 18 min., 35 per cent or less.

Table III shows the results of 5 Rose Bengal liver function tests, 3 total protein and albumin and globulin determinations, and 2 sulfur determinations.

1. The liver function tests showed dye retention in 4 of 5 determinations.

2. The blood protein determinations done on 3 patients were within normal values as was the distribution between the albumin and globulin fractions.

3. Inorganic and ethereal sulfates of the blood were found normal in 2 patients.

TABLE IV

CASE NO.	HB.	R.B.C.	W.B.C.	B.M.R.	ICTERIC INDEX	TEMPERATURE
1	35	1.54	5.6	plus 28	18	99
2	40	1.12	3.7	plus 13	15.2	98.8
3	40	1.48	4.8	plus 30	16	99
4	31	1.12	3.6	plus 21	7	98.8
5	58	2.35	3.6	0	20	98.2
6	55	2.08	5.8	plus 17	15	99.4
7	55	1.62	5.4	plus 6	7.1	98.4
8	56	2.32	5.6	plus 12	8	98.2

14	45	1.34	3	plus 28	18	99.2
15	54	1.85	3.8	plus 20	13.3	98.2

Table IV shows the basal metabolic rates of 15 patients and their icteric indices. The temperatures are included merely to indicate that at the time the basal metabolic rates were taken patients had no significant temperature.

1. Three of the 15 basal metabolic rate determinations only were normal, the other 12 being definitely elevated.

2. The icteric index determinations were normal in 4 of 15 patients on whom they were done.

SUMMARY

1. Total lipoids on all determinations were increased much above normal values. The fatty acids were very much diminished in all the determinations, as were the "lecithins" and the lipoid phosphorus. Cholesterol seemed normally distributed between the free and esterified forms, and showed values that were normal or slightly diminished. Only one cholesterol determination was below 100 mg.

2. One of 6 amino acid determinations showed a marked increase, while the other 5 were within normal values.

3. Calcium, phosphorus, uric acid, creatinine, sugar, chlorides, and carbon dioxide determinations were found normal. One nonprotein nitrogen and one urea nitrogen determination showed an increase above normal.

4. Total protein, albumin, and globulin values on 3 patients were normal.

5. Inorganic sulfates and ethereal sulfates on 2 patients were normal.

6. Four Rose Bengal liver function tests showed dye retention, and the fifth was normal.

7. The icteric index was increased in 73.3 per cent of the cases.

8. The basal metabolic rate was increased in 80 per cent of the cases.

9. One glutathione determination done on a patient who had hemoglobin 16 per cent and a red blood cell count of 0.710 showed 14.5 mg. per cent of reduced glutathione and none of the oxidized. The patient died two days later a section of liver taken from the autopsy and extracted with saline showed 168.7 mg. of reduced glutathione per 100 Gm. of liver. No oxidized glutathione was demonstrated in the saline liver extract.

NOTE.—Blood lipid determinations were all done by the Bloor method and were begun before the work of Christensen¹⁰ and Van Slyke and Folch¹¹ was published. This study of the lipoids in pernicious anemia is being continued in our laboratories by both the Bloor method and the modifications suggested by the authors mentioned.

LABORATORY METHODS

GENERAL

A SIMPLE NONTRAUMATIZING METHOD OF INDUCING PNEUMOCOCCIC INFECTION IN ALBINO RATS*

ELMER H. LOUGHLIN, M.D., SAMUEL H. SPITZ, M.D., AND
RICHARD H. BENNETT, M.D., BROOKLYN, N. Y.

WITHIN the past few years there have been developed new therapeutic agents for use in the treatment of pneumonia. Since there is great variability in the severity of human pneumococcic infections from year to year, it is necessary before these substances are used clinically to determine first their efficacy and toxicity under controlled conditions.

Tests in vitro partially demonstrate the efficacy, but obviously give no clue as to the toxicity of these preparations. To determine their toxicity and complete effectiveness in infection, experimental animals must be used.

It is well known that albino rats can be infected with pneumococci. Intraperitoneal inoculation and intrabronchial instillation of pneumococci are two procedures which have been used to infect them. The former causes a high incidence of infection and the dose of organisms can, with reasonable accuracy, be controlled. This method, however, does not reveal the effectiveness of therapy when there is pulmonary involvement.

With the latter method, originated by Nungester and Jourdonais,^{1,2} and used by Gross and Cooper,^{3,4} in the study of antipneumococcic drugs, in which pneumococci are suspended in gastric mucus, and instilled into a bronchus, infection is irregular and the recovery rate of the untreated or control animals is too high to warrant accurate evaluation of the therapeutic agent. Even though carefully performed, this procedure causes trauma which interferes with the interpretation of therapeutic efficacy and incidentally the pathogenesis.

A method, therefore, is required which, with a minimum of trauma, will produce a high incidence of pneumococcic infection with pulmonary involvement, and a constantly high fatality rate in infected animals. With these facts in mind, the following procedure is suggested.

METHOD

An unanesthetized rat, weighing about 300 Gm., is fastened with rawhide thongs to a small animal board (Fig. 1) designed for this procedure. A wire loop, attached to the undersurface of the board with a rubber band, is slipped

*From the Department of Internal Medicine, Long Island College of Medicine.

This work was made possible by a Fellowship Grant from the Lilly Research Laboratories, Indianapolis, Ind., and by the Dr. Frank E. West Fund, established by Miss Elizabeth Frothingham, and the John C. Warren Memorial Fund, established by Dr. Luther F. Warren, in memory of his son.

Received for publication, March 23, 1940.

over the animal's upper incisor teeth, and a strip of gauze is placed over the lower incisor teeth to pull the jaw open.

A pneumococcus culture, consisting of the washings of the peritoneal cavity of a white mouse infected with pneumococci,* is suspended in 15 c.c. of a physiologic solution of sodium chloride. This is sprayed into the pharynx and nares of the rat by means of an atomizer, the bulb being squeezed four times. This culture contains, as a result of the peritoneal inflammation, natural mucin in addition to the other components of an inflammatory exudate.

Fig. 1.

After preliminary treatment with soap and water, followed by acetone and alcohol, blood for culture is obtained from the tail of the animal by snipping off the tip with a pair of sterilized seissors. The drops of blood appearing at the cut end are placed directly on a blood agar plate and then streaked over the surface with a wire loop.

RESULTS

Of 131 animals thus sprayed 107, or 81.6 per cent, became infected as manifested by positive blood cultures.

Only those animals in which a growth of pneumococci in the blood culture was obtained were considered as having been infected. These animals invariably died. Although positive cultures have been obtained as early as four hours, the majority of the animals developed positive cultures between six and twenty-four hours after spraying.

*RI strain pneumococci were used in all experiments.

In the animals that died of pneumococcal infection, patches of pneumonia, sometimes involving an entire lobe or multiple lobes, were noted. In the majority of these animals this patchy pneumonic process was associated with empyema and purulent pericarditis. A purulent peritonitis sometimes developed and, in a few, meningitis occurred.

When the rats died of any of the above conditions a growth of pneumococci was obtained from the heart's blood.

DISCUSSION

The method of infecting rats with pneumococci in which pulmonic infection and bacteremia were common is nontraumatic, easily and rapidly performed, and permits, when necessary, large numbers of animals to be used for therapeutic studies.

Many investigators have sprayed the upper respiratory tract of animals attempting to produce pneumococcal pulmonary infections, but the results were generally unsatisfactory. In these cases the pneumococci used were grown in artificial media. Pneumococcal pneumonia in man is most frequently caused by pneumococci which have recently been in contact with a human host or carrier. It is known that organisms recently in contact with an animal host are more virulent than those grown in artificial media from eighteen to twenty-four hours. In order to simulate as closely as possible the conditions in human infection, when attempting to infect rats, we have used pneumococci in mouse peritoneal exudate, containing natural mucin, because this procedure appears to satisfy this requirement best. Not only are these organisms more virulent, but, as pointed out by Nungester and Jourdonais,² gastric mucin, when inoculated intrabronchially with pneumococci, hinders or prevents rapid phagocytosis of these organisms by the leucocytes of the infected animals. Such conditions probably exist in human infection.

SUMMARY

1. A simple nontraumatizing method of infecting rats with pneumococci has been described, in which pneumococcal exudate from the peritoneal cavity of the mouse is used because of the increased virulence of pneumococci recently in contact with an animal host and because of the natural mucin content of the exudate.
2. A high incidence of infection, 81.6 per cent, was produced as manifested by positive blood cultures, and at autopsy, by pneumonia, empyema, purulent pericarditis, peritonitis, or meningitis.

We wish to express our appreciation to Doctors Tasker Howard, J. Hamilton Crawford, Wade W. Oliver, and Arnold Eggerth for their aid and criticism in the preparation of this paper.

ORAL AND NASAL SIMULTANEOUS ASPIRATORS AND THEIR USE IN GASTROENTEROLOGY

MOSES EINHORN, M.D., NEW YORK, N. Y.

THE duodenum does not play a very important part in the physiology of digestion, except that it receives, aside from its own secretion, the combined secretions of the pancreas, liver, and biliary tract. It is here that the material coming from the stomach meets these various secretions. Thus the duodenum serves not only as a melting pot, but also as a conduit for conveying the combined material into the jejunum and ileum where the final process of digestion occurs.

Due to its position investigators made numerous attempts in the past to intubate the duodenum, among the first of whom were Hemmeter and Kuhn. The instruments they employed were crude and impractical and were therefore abandoned.

Max Einhorn experimented for a number of years with various tips and buckets, and finally, in 1909, developed the first practical apparatus which he called the duodenal pump.¹ Since that time eminent gastroenterologists have developed various types of tips, each claiming particular advantages, but all alike in principle, differing only in their size, weight, and number of perforations (Fig. 1).

In 1938 I developed a bucketless tube,² a radical departure from the other tubes in use. The apparatus is 50 inches in length (Fig. 2), 14 French in diameter, and its terminal end encases an elongated lead dropper, narrow and tapered above, but increasing in size below. Two openings, slotted in appearance, are situated just above the dropper, $\frac{1}{2}$ inch apart, on opposite sides of the tube.

The advent of the duodenal tube enabled physiologists, clinicians, and research workers to make a comprehensive survey and study of the functions of the stomach, liver, and pancreas. Yet, in their research work, they still felt the growing need for an instrument which would intubate both the stomach and duodenum, and permit a simultaneous withdrawal of their respective contents.

Max Einhorn³ in 1918 demonstrated an apparatus (Fig. 3A) by means of which the gastric and duodenal contents could be obtained at the same time. His aspirator consisted of a long soft rubber tube, about 12 French in diameter, divided into two separate canals, one leading to a terminal perforated capsule and the other to a perforated hollow metal connector situated about 25 cm. from the end of the tube. The proximal end of the tube branched off into two side tubes each provided with stopcocks, one marked *D* for the duodenum and the other *S* for stomach.

This double aspirator was provided with markings starting from the terminal end of the tube, and was introduced in the same manner as the usual duodenal tube, so that while the bucket entered the duodenum, the perforated connector lay within the limits of the stomach, thereby allowing the duodenal contents to be aspirated separately through the terminal tip and the gastric contents through the perforated connector.

For the simultaneous sampling of the gastroduodenal contents, Rehffuss first employed a method in which he used two separate tubes of different lengths. The patient first swallowed the longer tube in the usual way, and then, after it was ascertained that the tip had entered the duodenum, he swallowed the shorter tube.

DIAETER	FR. CH. 31.	23	29.	27	27.

Fig. 1.—Various tips used in gastrointestinal work.

To simplify it further, Rehffuss employed a second method⁴ whereby he attached the capsule of the shorter tube to the wall of the longer tube (Fig. 3B) at a distance of about 25 cm. from its end, so that when the distal tip was in the duodenum, the proximal capsule lay within the limits of the stomach.

In 1927 Kunstler, impressed by the findings of Garbat⁵ and Carlson⁶ that duodenal feeding promotes a rise of gastric acidity, suggested that constant and complete neutralization of gastric acidity in duodenal feedings could be accomplished by administering an alkaline solution by means of the continuous drip method. He designed for that purpose a special double tube.⁷ This consisted of an ordinary tube (Fig. 3C) to whose wall was vulcanized at a point 20 cm. from its bucket a shorter tube, smaller in caliber and open at its end for a distance of 70 cm., thus leaving the remaining 20 cm. free. His idea of treatment was to administer two-hour duodenal feedings through the longer tube and introduced a weakly alkaline solution for the full twenty-four hours by the drip method through the shorter tube.

The well-known Bayliss and Starling⁸ discovered the substance secretin which is formed when the acid contents of the stomach pass into the duodenum, which in turn, stimulates the production of pancreatic secretion and its enzymes.

This work has been confirmed in its major aspects by most physiologists and, hence, secretin has been the substance used when a substantial increase in the volume of the pancreatic secretion was desired.

Fig. 2.—Einhorn's bucketless lead weighted gastroduodenal tube.

Fig. 3.—Various simultaneous gastroduodenal aspirators.

The Swedish investigators, Ågren and Lagerlöf,⁹ made an extensive study of pancreatic secretion in man after intravenous administration of secretin and designed a special double tube for that purpose (Fig. 3D, E). Their tube consisted of two tubes free for the first 20 cm. and fused together for a distance of 70 cm. The duodenal side, which extended for a distance of 20 cm. and had a capsule at its end, featured seven oval-shaped openings on its last 8 to 10 cm. of tubing. The gastric tube had five to six openings on its side. The whole of this 70 cm. of fused tubing was encased in a thin rubber sheath to facilitate swallowing. In order to accelerate the entrance of the duodenal tube into the duodenum, they tied to its end a fine silk cord, 10 cm. in length,

to which was attached a lead ball 8 mm. in diameter. The tube was swallowed in the usual way, and when the tip entered the duodenum, the openings of the gastric tube remained in the stomach area.

In this country, Diamond¹⁰ recently made extensive studies on the use of secretin as a clinical test of pancreatic function and used a specially designed gastroduodenal tube. His apparatus permitted the separate collection of gastric and duodenal contents by preventing the admixture of the two secretions, thus assuring the collection of pure duodenal juice (Fig 3*F*).

Fig. 4.—Einhorn's double channel esophageal lavage tube.

In my article on "The Treatment of Cardiospasm,"¹¹ I described a double lumen tube (Fig. 4) for esophageal lavage. Its basic principle is the same as that which has for some time been used in colonic irrigation and which has subsequently been adopted by Miller and Abbott for intestinal intubation. The tube is 28 French in diameter, 30 inches in length, and is bisected into two distinct canals. One of the canals terminates at a point four inches short of the tip, while the remainder of its lumen is filled with solid rubber. Immediately above this solid portion the walls feature a few wide openings. The second canal extends to the very end of the tube and has at its terminal end a few oval perforations.

The idea occurred to me that by combining the main features incorporated in the bucketless and double lumen esophageal tube, I would have a very simple and efficient either oral or nasal simultaneous gastroduodenal aspirator (Fig. 3*G*, II).

The oral tube* (Fig. 5*F*) is 50 inches in length, 16 and 18 French in diameter, semisoft in consistency, flexible, and of good resiliency. Its lumen

*Made by Clay-Adams Co.

is equally divided into two channels (Fig. 5A), semilunar in shape. Its terminal end, 1 inch in length, encases an elongated drop-shaped lead sinker (Fig. 5Ga), narrow and tapered above, but increasing in size at the bottom, this portion including the sinker with its layer of rubber being 150 grains in weight, 1 inch in length, and 27 French in diameter at the bottom, the top being of the same size as the tube. The duodenal side of the double channel extends down to the top of the sinker and has three oval openings slotted in appearance and $\frac{1}{2}$ inch apart. The small space between the sinker and the lower opening is filled with rubber. The gastric side of this double channel ends at a point about 7 inches above the sinker; the remainder of its lumen is filled with lead shot (Fig. 5Gb). Immediately above the lead-filled portion, there are three openings, oval in shape and $\frac{1}{2}$ inch apart.

Fig. 5.—Einhorn's nasal and oral simultaneous gastroduodenal aspirators.

The nasal tube (Fig. 5C) is designed in the same manner as the oral, except that it is 16 French in diameter and terminates in a catheter-like tip (Fig. 5Da), which is made of solid impregnated lead rubber for $2\frac{1}{2}$ inches.

For the oral tube the markings are as follows: the one-ring mark is placed 17 inches from the end of the tube, and represents the distance from the lips to the cardia; the two-ring mark, at 28 inches, represents the distance from the lips to the pylorus; and the three-ring mark, at 33 inches, permits 5 inches of the terminal end of the tube to enter the duodenum (Fig. 5H) and leaves a space of 3 inches from the lower opening of the gastric channel.

In the case of the nasal tube the one-ring mark is placed at 19 inches, the two-ring mark at 30 inches, and the three-ring mark at $36\frac{1}{2}$ inches. It is understood, however, that the physician's judgment should always determine the amount of tubing for each individual and he should not rely entirely on the markings.

The special double channel connector (Fig. 5B) consists of two narrow metal tubes soldered together in the middle, branching off distally into two distinct separate canals, each of which is cemented into its proximal opening of the tube to render it airtight. Proximally, the connector bifurcates into two channels, one representing the gastric outlet and the other the duodenal.

ADVANTAGES

Oral Tube.—1. The tube is simple in construction and no fusion of tubes is necessary, thereby facilitating swallowing.

2. The fear the patient usually experiences that the metal bucket may become detached is eliminated, as the lead dropper is encased in the tube.

3. Swallowing of the tube is accelerated because of the weight of the dropper, which is sufficient to permit its passage through the esophagus with no discomfort to the patient.

4. The tube maintains its intended course along the stomach pathway because of the lead-shot compartment and the weight and proper arrangement of the lead sinker, which keeps it in its proper place in its progress to the pyloric opening.

5. Due to the special distribution of the weight of the sinker, which anchors the tube securely in the duodenum, there is no likelihood of regurgitation of the bucket from the duodenum into the stomach, as is usually the case with other tips.

6. No discomfort is encountered at the glottis upon removal of the tube, because of its tapered shape and gradual decrease in size at the neck.

7. There is no need for silver- or gold-plating the metal bucket to avoid impairment of the mucous membrane, since the sinker is encased in rubber.

8. The openings of the tube have rubber margins, thereby eliminating the possibility of cutting the mucous membrane upon suction, as is usually the case with metal buckets.

Nasal Tube.—1. The $2\frac{1}{2}$ inch solid rubber catheter-shaped tip at the terminal end facilitates the introduction and passage of the tube through the nares.

2. The weight of the lead-impregnated rubber tip and the lead-shot compartment facilitates the passage of the tube through the esophagus, maintains it in its proper position along the stomach pathway, and aids its entrance into the duodenum.

3. There is less possibility of the lower part of the tube regurgitating into the stomach as the weight of the solid lead-impregnated rubber portion and the lead-shot compartment keeps it securely in the duodenum.

TECHNIQUE

Oral Intubation.—The patient reports on an empty stomach and is placed in an upright position on a chair or in bed, and is instructed to protrude his tongue to form a groove. The operator seizes the terminal lead sinker, previously moistened, between the thumb and forefinger, and places it on the grooved portion of the tongue. The patient is instructed to open his mouth wide and say "Ah." The operator then inserts the sinker far enough into the

mouth under the uvula and instructs him to close his mouth and concentrate on the act of swallowing. The tube, due to its lead weight, will be carried down slowly through the esophagus.

As soon as the tube has reached the first-ring mark, the patient is placed in a reclining position on the right side, with the right leg and knee stretched straight and the left leg and knee flexed, overlapping the right.

The patient is instructed to swallow the tube very slowly, an inch at a time, over a period of twenty to twenty-five minutes, until the third-ring mark is reached, so that the terminal end will enter the duodenum.

After the patient has swallowed a few inches of the tubing while lying on the right side, it is a good practice to inject a small amount of lukewarm water through the gastric canal in order to relax the pyloric opening and stimulate the peristaltic action of the stomach, thereby facilitating and accelerating the entrance of the terminal portion of the tube into the duodenum.

Upon completion of the examination, the operator withdraws the first seven inches of the tube while the patient is in a recumbent position, and the balance of the tube while the patient is in the upright position.

In case no bile is obtained, the operator should withdraw the tube up to a point midway between the first- and second-ring marks and then instruct the patient to swallow it again.

Nasal Intubation.—The terminal end of the tube, which has previously been dipped in glycerin, is introduced through the nose for a distance of six inches, and the patient is then asked to simulate the act of swallowing, while the operator pushes the tube which will be carried down slowly in the esophagus because of its lead-weight compartment.

As soon as the first-ring mark is reached, the patient is turned on the right side and the same procedure is followed as in oral intubation.

Tests for Determining the Entrance of the Terminal Tip Into the Duodenum.—1. It is possible to determine the entrance of the tip into the duodenum with the aid of fluoroscopic and x-ray examinations. Although this method is undoubtedly reliable, I believe that it should not be used in routine practice, since in the course of removal of the patient to the x-ray room and of manipulation, the terminal portion of the tube may easily slip back into the stomach even with the lead-weighted tip.

2. By observing the characteristic differences in color, viscosity, and reaction of both specimens obtained from the two outlets. The duodenal specimen will be viscid, golden yellow in color, and negative to Congo red, whereas the gastric specimen will be clearer, perhaps bile-tinged, but positive to Congo red.

3. If, after injecting a mixture of barium or any other colored solution into the duodenal outlet, no return is obtained on the gastric side, the terminal tip has entered the duodenum.

USES

Medical.—1. For obtaining a simultaneous specimen from the stomach and duodenum.

2. For determining the effect on the duodenal contents of substances introduced into the stomach and vice versa.

3. In peptic ulcer cases where duodenal feeding and intermittent or continuous neutralization by drip method is desired.
 4. In cases of gastric atony, nervous dyspepsias, or any form of vomiting where duodenal gavage and gastric drainage are indicated.
 5. In biliary drainage.
 6. In cases where esophageal or gastric continuous lavage is required.
- Surgical*.—1. In preoperative and postoperative gastrointestinal and abdominal surgery, where simultaneous and continuous gastrointestinal drainage¹² is wanted.
2. In cases where tubal feeding and drainage are required.
 3. In cases of gastroenterostomy.

I wish to express my gratitude to Mr. L. T. Hillborn, president of the Clay-Adams Co., for his kind cooperation in the development of the tubes

A STUDENT SPHYGMOSCOPE*

ALRICK B. HERTZMAN, PH.D., ST. LOUIS, MO.

THE desirability of providing the student with laboratory experience with the type of sphygmomanometer devised by Erlanger led us some years ago to modify the sphygmoscope developed by Erlanger and Meek¹ so that advantage could be taken of apparatus available in the student equipment.

Fig. 1.—The student sphygmoscope.

The sphygmoscope shown in Fig. 1 has been in use for twelve years with a minimum of servicing by the mechanic. It is essentially the same as that of Erlanger and Meek, excepting for the arrangement of the control valve. The parts are metal. Brass tubing is used instead of glass. The rubber membrane surrounding the inner tube may be quickly made from sheet rubber of suitable thickness by cementing overlapping edges. The control valve replaces the compressive compound stopcock in the Erlanger sphygmomanometer. A capillary glass or metal stopcock placed on a side arm in the connection to the tambour provides a leak which may be easily adjusted so that it protects the tambour against slow large changes in the volume of the outer chamber of the sphygmoscope, but does not interfere with the recording of the oscillations; or a similar needle point valve may be soldered on the cup of the tambour to serve the same purpose. The sphygmoscope and control valve are mounted on a board. On all dimensions are 8 by 4½ by 2½ inches, permitting compact storage.

Operation of Control Valve.—Three positions are available:

(1) Exhaust position (shown). Arm cuff and outer chamber of sphygmoscope are in connection with the outside through exits 1 and 3. A baffle plate in the central outlet of the cock prevents the gust of air from the arm cuff from disturbing the tambour. This position is used for deflating the arm cuff when using the intermittent escapement method. The diameter of exit 1

*From the Department of Physiology, St. Louis University School of Medicine.
Received for publication, April 13, 1940.

85 mm.

Fig. 2.—Illustrative record made with student equipment. Lower record sphygmoscope oscillations. Note flattening in diastolic portion of curve at X, and its disappearance when diastolic pressure (auscultatory) is reached. Upper record: arm cuff pressure. Middle record: auscultatory systolic and diastolic pressures at first and second signals.

Fig. 3.—Sections from optical record. A, Auscultatory systolic pressure (double signal) at 128 mm. Hg. B, Cuff pressure 110 mm. Hg. C, Auscultatory diastolic pressure (double signal) at 93 mm. Hg.

made small enough so that the deflation is readily controlled. (2) Intake position. Exit 1 is in line with the scratch mark IN. Exit 2 is in connection with the outer chamber of the sphygmoscope and so prevents the large volume changes here during inflation of the arm cuff from affecting the tambour. (3) Operating position. Exit 1 is in line with the scratch mark OP. All exits are closed in this position. The oscillations of the sphygmoscope are now transmitted to the tambour. This position is used when the method of continuous escapement is employed, the tambour leak being adjusted in proportion to the rate of fall in arm cuff pressure which is controlled by the air escape valve on the cuff. The method of intermittent escapement may also be used with this position. This position is also used when one wishes to record continuously variations in arterial pressure. The sphygmoscope is very useful for student experiments of the latter type.

Criteria of Systolic and Diastolic Pressures With Sphygmoscope.—These can be studied by the student by arranging to record arm cuff pressures with a recording manometer, and signaling auscultatory systolic and diastolic criteria while the sphygmoscope oscillations are being recorded. A typical performance using a Marey tambour (Harvard Apparatus Co.) is illustrated in Fig. 3. The systolic sign, as pointed out by Erlanger, seems to be "the first clear increase in the spread of the limbs at the base of the pulse wave." The diastolic criteria of Erlanger are less apparent. Many records have shown that a flattening in the catacrotic portion of the pulse curve disappears at pressures very near those at which the Korotkow sounds become dull and muffled. This is more clearly shown in the optical records of Fig. 3. The wave is completely supported throughout the pulse cycle at lower pressures. This relationship is not entirely regular. The flattening may disappear either slightly above or slightly below the pressure at which muffling occurs.

DEXTROSE YEAST EXTRACT MEDIUM FOR THE ISOLATION OF FUNGI FROM SPUTUM*

DIRAN YEGIAN, D.V.M., AND JOSEPH M. KURUNG
RAY BROOK, N. Y.

SABOURAUD'S medium with a pH of 5.5 is in general use for the isolation of fungi from the sputum; however, it inhibits only to a limited degree the growth of bacteria commonly found in the sputum when incubated at a temperature of 37° C. One or more transplants may be required before the fungus is finally recovered in pure culture. The growth of the bacteria may be further inhibited by gently swabbing the surface of the medium with a tenth-normal solution of hydrochloric acid previous to the implantation of the sputum. The application of the acid to the medium does not interfere with the growth of fungi. The foregoing observation suggested the advisability of materially increasing the acidity of Sabouraud's medium for the recovery of fungi from the sputum.

A series of experiments disclosed that the optimal pH for the growth of fungi and the prevention of bacterial growth is 4.0. In order to bring Sabouraud's medium to this pH, it is necessary to modify in part the standard method of preparation as follows:

Dissolve the peptone and agar in distilled water by heating in the autoclave for fifteen minutes at 15 pounds pressure. Add a sufficient amount of an aqueous solution of 20 per cent dextrose to bring the dextrose content of the medium to 4 per cent. Under sterile conditions, and while the medium is still in the liquid state, adjust to the desired pH. The medium can be poured immediately or allowed to solidify in the container for future use.

The adjustment of Sabouraud's medium to a pH of 4.0 in the manner here described requires detailed attention and considerable time. Moreover, Sabouraud's medium is not kept in stock in many laboratories and consequently is not always available to the physician. These objections are overcome by the following simple liquid medium:

Dextrose	8.0 Gm.
Sodium chloride	1.7 Gm.
Yeast extract (Difco)	0.5 Gm.
Distilled water to make	200 c.c.
Adjust to pH 4.0	

The above medium should not be diluted when determining the pH, since it is buffered to only a slight extent if at all, and the addition of water would decrease the hydrogen-ion content.

The experiments here outlined indicate the relative value of Sabouraud's medium with pH values of 5.5 and 4.0, and dextrose-yeast-extract medium with

*From the New York State Hospital for Incipient Pulmonary Tuberculosis.
Received for publication, April 5, 1940.

a pH of 4.0 in the recovery of fungi from the sputum. In a few instances fungi present in the sputum, for example, the *Penicillium*, grow better at room temperature than at 37° C. It is advisable, therefore, as a routine procedure, to grow the cultures at both these temperatures.

Fig. 1.—Fungus and bacterial colonies on Sabouraud's plate with pH 5.5.

Fig. 2.—Pure culture in liquid media with pH 4.0. A, *Aspergillus fumigatus*; B, *Coccidioides immitis*.

Fifty specimens of tuberculous sputa were collected in sterile Petri dishes. A purulent portion from each specimen of sputum was implanted on these three media. The implanted medium was incubated at 37° C. and observed

daily for a period of ten days. Sixteen of the fifty specimens of sputa yielded cultures of *Monilia* on each of the three media. In no instance on Sabouraud's medium with a pH of 5.5 were the colonies of *Monilia* found in pure culture; but numerous colonies of bacteria were present on all fifty plates. The number of bacterial colonies was greatly reduced on Sabouraud's medium with a pH of 4.0, and nine of the sixteen specimens gave pure cultures of *Monilia*. Sputum implanted in fifty tubes of dextrose-yeast-extract medium gave no bacterial growth as determined by cultures on nutrient agar plates, and the *Monilia* was recovered in pure culture from sixteen tubes.

Cultures of various fungi (*Coccidioides immitis*, *Aspergillus fumigatus*, *Aspergillus niger*, *Oidium*, *Monilia albicans*, *Geotrichum*, *Cryptococcus*, *Torula*, *Streptothrix*, *Actinomyces*, and *Sporotrichum*) were intimately mixed with sputa from tuberculous patients and implanted on Sabouraud's medium with pH values of 5.5 and 4.0, and on dextrose-yeast-extract medium with a pH of 4.0. Colonies of each of the above-mentioned fungi were found on all three media. However, many bacterial colonies were present on all the plates on Sabouraud's medium with a pH of 5.5. The bacterial colonies were decidedly fewer in number on the Sabouraud's plates with a pH of 4.0, while on the dextrose-yeast-extract medium with a pH of 4.0, no bacterial growth was demonstrated. The above experiments indicate that the liquid dextrose-yeast-extract medium with a pH of 4.0 is superior to the solid Sabouraud's medium for the isolation of fungi from the sputum.

The dextrose-yeast-extract medium here described is composed of a few simple ingredients, is easily prepared, and affords a ready means for the recovery of fungi from the sputum.

AN EFFICIENT DISSECTING AND OPERATING TABLE*

MAX L. SWEAT, LOGAN, UTAH

THERE is need for an efficient dissecting and operating table. The one built by us has particular advantages over those now on the market. Its advantages are: (1) The mechanical construction throughout is of utmost simplicity. (2) The whole mechanism is of metal. (3) The table top can be instantly adjusted to any plane—slightly short of vertical. (4) The stand may be adjusted for height. (5) The table may be used for either dissecting or operating. (6) The animal to be dissected can be rigidly fastened to the table in only a few seconds, and once in position the natural tension of its limbs prevents any loosening of the hold. (7) Both the stand and the table top can be sterilized.

When dissecting, the hooks are inserted directly into the animal's legs; and when operating, they are inserted into adhesive tape wrapped around the lower part of the legs. Several mechanical devices for holding the legs of animals without harming them were investigated, but the adhesive tape was

*From the Department of Bacteriology and Biochemistry, Utah State Agricultural College. Received for publication, April 22, 1940.

found the most practical. It neither harms the animal nor requires tedious adjusting, and is easily removed after the operation by means of ether.

Fig. 1.

DESCRIPTION

1. *Table Top.* This is made of 18 gauge stainless steel (Fig. 1). The top is reinforced with $\frac{1}{2}$ inch 90° angular strips of the same metal running around the bottom 1 inch from the edges. The size 10 by 14 inches is suitable for guinea pigs, rats, and smaller animals. Heavier gauge and larger dimensions are required for tables to accommodate large animals. Adjustments are such that

even a small mouse may be fastened to a large table, but unless work on many size animals is to be done it is advisable to make the table near the size of the animal to be used. Around the edges of the table are V-shaped grooves $\frac{3}{16}$ inch deep and 1 inch apart. These serve to hold the bead chain in tension against the animal. Fig. 1 shows the retractors, hooks, and chains in position on the table top.

FIG. 2.

2. *Ball and Socket.* The ball is fastened to a rod welded on the bottom of the table top. The split socket is fastened to the inner stand tube. The ball and socket enables the tipping of the table in any direction. This is done by loosening or tightening the adjusting screw. A two inch ball and socket serves well for a table of this size.

3. *Adjusting Screws.* The screws are simply threaded $\frac{3}{8}$ inch metal rods with handles. Just above the threads a projection is welded to keep the rod from going past its threads in the first lug which is slightly larger than the rod

and contains no threads. This lug is soldered on the right of either the slit of the socket or outer stand tube. The second lug, which is soldered on the left of the split, has threads of the same size as the rod. By turning the rod, the distance between the welded projection and the second lug is shortened, thus decreasing the size of the socket or outer tube as the case may be.

4. *Stand Tubes.* These are two; the inner, $1\frac{5}{16}$ inches; the outer, $1\frac{1}{2}$ inches in diameter. Both are 2 feet long. Ordinary chromium-plated brass plumbing tubing serves well. By loosening and tightening the adjusting screw, the inner tube may be raised or lowered to the desired height.

5. *Base.* This is made of two pieces of cast iron. The smaller, 2 by 4 by 4 inches, is fastened by bolts to the larger, 2 by 10 by 10 inches. The stand tube is welded to the base.

6. *Hooks.* These are made from ordinary No. 6 bait fishhooks by filing off the prongs and bending the eyes to right angles, and are then fastened to the chains.

7. *Retractors.* They may be made from 22 gauge stainless steel. They are used in the same manner as ordinary dissecting retractors.

8. *Bead chain.* This is the ordinary bead or ball chain used on light strings, sink stoppers, and key chains.

It will be noticed there is no device on this apparatus for holding the heads of animals. The hooks may be used for this if the animal is to be dissected; if to be operated on, a wide piece of adhesive tape with a hole corresponding to the point of incision in the animal's head may be wrapped entirely around the head and hooks may be inserted in the tape.

I wish to acknowledge the helpful advice and friendly criticism of Dr. J. E. Graves.

SOME IMPROVED METHODS FOR STAINING VAGINAL SMEARS*

GEORGE N. PAPANICOLAOU, M.D., PH.D., NEW YORK, N. Y.

ABOUT three years ago Mrs. Dorothy Fuller, who was at that time working with Dr. Florence Sabin at the Rockefeller Institute, gave me a series of vaginal smears for examination. These smears were stained by Mrs. Fuller with one of Foot's modifications of Masson's trichrome method.¹ This method was briefly as follows:

Iron alum solution in oven 45° to 50° C. five minutes. Wash. Hematoxylin in oven five minutes. Picric acid five to ten minutes. Wash. Ponceau de xyldine-acid fuchsin five minutes. (Fuller used a solution of equal parts of ponceau de xyldine-acid fuchsin and 1 per cent acetic acid.) Rinse in distilled water. Phosphomolybdic acid five minutes. Rinse in distilled water. Light green five minutes. Rinse in distilled water. Acetic acid two minutes. Rinse in tap water, alcohols, and xylol. Mount in balsam.

Smears stained by this method showed a very good differentiation of the cornified cells. A double coloration of these cells was obtained; some cells

*From the Department of Anatomy, Cornell University Medical College, New York. This study has been aided by the Committee for Research on Sex Problems of the National Research Council.

Received for publication, October 11, 1940.

were pink, some were orange, and others took on intermediate shades. Further experimentation was, however, necessary for evaluating the meaning and the importance of this differential staining of the cornified cells.

Unfortunately, the foregoing method was too long and complicated to be adopted as a standard method for staining vaginal smears. Another disadvantage was its failure to secure a differential staining of the mucous cells, which are characteristic of the early estrous stage in some lower mammals, more particularly in the guinea pig. This disadvantage would not, however, apply to human vaginal smears or to smears of such animals in which the mucous cell type is absent.

The eosin-water blue staining method which I suggested in 1933² permits a good differentiation between the basal cells which are stained blue, the mucous cells which are stained purple, and the cornified cells which are stained with various shades of eosin red. This method consists in treating vaginal smears, previously stained in hematoxylin, with a 0.5 per cent aqueous solution of eosin (Grübler) for four minutes and then, after rinsing in water, in a 0.5 per cent aqueous solution of water blue (Grübler) for about one minute. Shortening of the treatment with water blue would tend to intensify the staining of the cornified elements.

This staining method, though relatively short and simple, could be further simplified through a combination of eosin and water blue. The following mixture gives satisfactory results*: 1.25 Gm. of eosin (Grübler), 0.5 Gm. of water blue (Grübler), 2 Gm. of phosphomolybdic acid, and 350 c.c. of distilled water. An increase in the amount of eosin would result in sharper staining of the cornified cells.†

Since it was found that a satisfactory combination of eosin and water blue could be achieved through the acidification of the mixture, an increase in the color range of the cornified cells was attempted by the addition of orange G, acid fuchsin, and some other stains. By modifying the percentages of the various stains and by adding the proper amount of acid, various shades of orange, pink, and red were obtained. Aniline blue, light green, and other stains were substituted for water blue. The coloration of the noncornified cells could thus be changed.

After long experimentation with over 400 combinations of various imported and domestic stains, a number of satisfactory preparations were developed, some of which are described here. These preparations offer an advantage in that they can be modified to some extent for the purpose of obtaining suitable differentiation of one or another cell type.

While this work was in progress, Shorr^{3, 4} described two staining methods for vaginal smears, based on a more recent modification of the Masson trichrome method by Foot.⁵ The two methods suggested by Shorr are very satisfactory for human smears and are considerably shorter than the method

*This stain is also satisfactory as a general tissue stain.

†A corresponding mixture consisting of domestic stains (National Aniline and Chemical Co.) can be prepared as follows: Aniline blue, water soluble, 60 c.c. of a 0.5 per cent aqueous solution; yellow eosin, 300 c.c. of a 0.5 per cent aqueous solution; phosphomolybdic acid, 1.65 Gm. For intensifying the staining of the cornified cells, the relative amount of eosin should be raised.

used by Fuller. The second of the two methods⁴ takes about six minutes after staining with hematoxylin, but it requires the following steps: (1) one minute in 1 per cent Biebrich scarlet and 0.4 per cent orange G; (2) rinsing in water; (3) one minute in equal parts of phosphotungstic and phosphomolybdic acids; (4) rinsing in water; (5) two minutes in 0.25 per cent fast green FCF; (6) one minute in 1 per cent acetic acid. With the counterstains described herein the staining takes about two minutes and consists of only one step.

A. Solutions made of partly imported and partly domestic stains.

I. Stain DA 15.

Light green F S	Grübler	0.5% Solution	20 c.c.
Orange G	Grübler	0.5% Solution	20 c.c.
Acid fuchsin	Grübler	0.5% Solution	20 c.c.
Eosin yellowish	National Aniline and Chemical Co.	0.5% Solution	40 c.c.
Acid phosphomolybdic	Merck		0.45 Gm.

II. Stain CY 18.

Wasserblau 6B extra	Grübler	0.5% Solution	10 c.c.
Orange G	Grübler	0.5% Solution	25 c.c.
Acid fuchsin	Grübler	0.5% Solution	25 c.c.
Eosin yellowish	National Aniline and Chemical Co.	0.5% Solution	60 c.c.
Acid phosphomolybdic	Merck		0.75 Gm.

III. Stain DF 11.

Aniline blue, water soluble	Grübler	0.5% Solution	12 c.c.
Orange G	Grübler	0.5% Solution	25 c.c.
Acid fuchsin	Grübler	0.5% Solution	25 c.c.
Eosin yellowish	National Aniline and Chemical Co.	0.5% Solution	60 c.c.
Acid phosphomolybdic	Merck		0.6 Gm.

B. Solutions made of domestic stains.

IV. Stain DA 19.

Light green SF yellowish	National Aniline and Chemical Co.	0.5% Solution	12 c.c.
Orange G	National Aniline and Chemical Co.	0.5% Solution	24 c.c.
Acid fuchsin	National Aniline and Chemical Co.	0.5% Solution	20 c.c.
Eosin yellowish	National Aniline and Chemical Co.	0.5% Solution	40 c.c.
Acid phosphomolybdic	Merck		0.45 Gm.

V. Stain DF 20.

Aniline blue, water soluble	National Aniline and Chemical Co.	0.5% Solution	16.5 c.c.
Orange G	National Aniline and Chemical Co.	0.5% Solution	25 c.c.
Acid fuchsin	National Aniline and Chemical Co.	0.5% Solution	25 c.c.
Eosin yellowish	National Aniline and Chemical Co.	0.5% Solution	60 c.c.
Acid phosphomolybdic	Merck		0.7 Gm.

VI. Stain DF 32.

Aniline blue, water soluble	National Aniline and Chemical Co.	0.5% Solution	12 c.c.
Orange G	National Aniline and Chemical Co.	0.5% Solution	25 c.c.
Acid fuchsin	National Aniline and Chemical Co.	0.5% Solution	21 c.c.
Eosin yellowish	National Aniline and Chemical Co.	0.5% Solution	42 c.c.
Phosphotungstic acid	Merck		0.1125 Gm.
Phosphomolybdic acid	Merck		0.225 Gm.

The solutions I to VI are more appropriate for staining human vaginal smears. For lower mammals or rodents, an increase in the percentage of the blue or green basophilic stain secures a better differentiation of the basal cells.

The complete staining procedure is as follows:

1. Smears are fixed immediately (before drying) in equal parts of 95 per cent alcohol and ether* (original method of Stockard and Papanicolaou⁶). Rinse in 70 per cent and 50 per cent alcohols and in distilled water.

2. Ehrlich's hematoxylin, one to two minutes (other hematoxylin preparations may be used).† Rinse in distilled water. Rinse a few times in one per cent hydrochloric acid (may be omitted). Keep in running water about five minutes or in lithium carbonate (3 drops of a concentrated aqueous solution in 100 c.c.) for one minute. Subsequent staining may be affected if slides are left too long in running water.

3. Rinse in distilled water. Stain in one of the counterstains (I to VI) for two minutes. (Staining for five minutes or even longer is advised when smears are thick.) Rinse in water.

4. Rinse in dioxane ten to fifteen times until smears are clear. Rinse in absolute alcohol and xylol. Mount in clarite, Canada balsam, or gum dammar.

The use of dioxane instead of ascending alcohols for dehydration shortens the staining process and improves the differential staining in human smears. It is less desirable for smears of rodents, since it modifies the staining reaction of the mucous cells.

The staining time may be considerably shortened by the omission of the hematoxylin. Slides are stained as follows:

1. Fix smears in alcohol-ether solution for from one to two minutes. Rinse well in 70 per cent and 50 per cent alcohols, and in distilled water.

2. Stain in DF 50‡ or in one of the other counterstains (I to VI) for two to three minutes. (Staining for five minutes or even longer is advised when smears are thick.) Rinse in water.

3. Rinse in dioxane until clear, then in absolute alcohol, xylol, and clarite. Nuclei are stained red, erythrocytes orange, cornified cells red, pink, or orange, and basophile cells green or blue. The nuclei are not as dark and the cell outlines are not as sharp as with hematoxylin, but the cornified cells are more prominent and the basal cells are more transparent.

When a prompt examination of a smear is desired for diagnostic purposes this short method is of particular advantage, for it requires only about three

*Good fixation may be obtained within one to two minutes, though a fixation of from five to fifteen minutes, depending on the thickness of the smear, is more desirable. Slides may be kept in the fixative for several hours or even days without being harmed. Fixation for more than a week or two may, however, change the staining reactions of some of the cells.

†Harris hematoxylin prepared with domestic hematoxylin and ammonium alum gives very good results.

‡VII. Stain DF 50 (particularly adapted to staining without hematoxylin).

Aniline blue, water soluble	National Aniline and Chemical Co.	0.5% Solution	16 c.c.
Orange G	National Aniline and Chemical Co.	0.5% Solution	17 c.c.
Acid fuchsin	National Aniline and Chemical Co.	0.5% Solution	23 c.c.
Eosin yellowish	National Aniline and Chemical Co.	0.5% Solution	4½ c.c.
Phosphomolybdic acid	Merck		0.2 Gm.
Phosphotungstic acid	Merck		0.2 Gm.

to four minutes. It was developed in cooperation with Dr. Ralph C. Benson, of the Department of Gynecology, Cornell Medical College, who finds it especially suitable for preliminary examinations at the Woman's Clinic of the New York Hospital.

The method can be further simplified by the use of dropping bottles instead of staining jars. The stain is poured over the smear, as in bacteriologic staining. The use of dropping bottles prevents evaporation or dilution of the stain and makes its periodic replacement unnecessary. In washing the slides, fluids should be poured on the reverse side so as not to wash off the smear.

The differential staining of the cornified cells is of value in interpreting human vaginal smears in both normal and pathologic cases. Totally cornified cells, like the so-called eosinophilic cells of rodents, show a strong affinity to the orange color. The term "eosinophilic" thus appears to be inappropriate for specifying these cells. The term "acidophilic" or "orangeophilic" would be more accurate. Cells of this type are found in the human vagina more frequently during premenstruum or during pregnancy.²

In the normal cycle the orange shades tend to predominate during the second half of the cycle. Some local irritations or infections, abortions, and certain pathologic conditions associated with bleeding are characterized by a prevalence of pink or red shades. The cornified cells, which usually appear in large numbers after a *Trichomonas* infection, show a preference for orange shades. A similar preference is shown by the cornified cells which follow a prolonged estrogenic treatment. Drying of the cells modifies their staining reactions. For this reason, dry smears cannot be satisfactorily stained with the afore-mentioned methods. Most dry cells take an orange or yellowish color. This may often be a source of error in evaluating smears which were partially dried up prior to fixation.

The general adoption of a standard staining method for vaginal smears was advocated by Schneider.⁷ This would undoubtedly result in a more uniform description of vaginal smear findings by various workers in the field. It would be, however, difficult to reach a general agreement on the superiority of any one of the staining methods which have been thus far proposed. Besides, each one of these methods will probably offer some specific advantage over the others. The DF 50 stain without hematoxylin may be recommended for its shortness, but it does not stain nuclei as well as hematoxylin. This, though a disadvantage, may be of real advantage in the study of certain smear types. It keeps the leucocytes in the background and makes the epithelial cells stand out more distinctly. It may be used profitably in the evaluation of estrogenic or other endocrine treatments, and of cellular changes occurring during the various phases of the sex cycle. For gynecologic diagnostic work* other stains, like DF 32, DF 20, or CY 18 after hematoxylin, would be preferable, since they would bring out more cytologic details.

*The usefulness of the vaginal smear method in gynecologic diagnosis is now being investigated in cooperation with Dr. Herbert F. Traut of the Department of Gynecology.

CHEMICAL

THE SOLUTION AND DIAZOTIZATION OF BILIRUBIN IN CHLOROFORM AND OTHER ORGANIC SOLVENTS*

ROGER S. HUBBARD, PH.D., AND NORMAN HEILBRUN, M.D., BUFFALO, N. Y.

AS PART of a study of bilirubin extracted from serum by chloroform, as described in a recent note,¹ an attempt was made to study the diazo reaction of the bilirubin in such extracts. Difficulty was encountered in obtaining colors comparable with those of the various permanent standards which have been recommended from time to time,²⁻⁴ even when various buffer systems to insure the correct hydrogen-ion concentration were used. Attention was, therefore, turned to the use of standards prepared from bilirubin dissolved in chloroform, as originally recommended by van den Bergh.² The bilirubin used in these experiments† was not easily completely soluble in chloroform. Without the aid of heat, the strongest solutions that could be prepared contained about 10 mg. of bilirubin per 100 c.c. Solutions with concentrations of this magnitude were used by van den Bergh in standardizing the method when it was first described² and have been more recently employed by Malloy and Evelyn⁵ in a photoelectric modification of the technique. By the use of heat, solutions containing 40 to 50 mg. per 100 c.c. could be prepared.‡ The long period of heating sometimes found necessary seemed inadvisable when working with a compound such as bilirubin, and we wished, if possible, to prepare stock solutions containing even higher concentrations of bilirubin than this. Bilirubin in alkaline solvents, both inorganic and organic, were quite unstable. It was finally found that if phenol were added to various organic solvents, very strong solutions of bilirubin could be prepared, and that the stability of such solutions in diffused light was much greater than in the pure solvents. This increased solubility and stability were demonstrated in solutions in chloroform, xylene, acetone, and methyl and ethyl alcohol.

Most of the experimental work was done upon bilirubin dissolved in a mixture of chloroform and phenol, made by dissolving 10 Gm. of phenol in 100 c.c. of chloroform. This solution, prepared freshly before use, would dis-

*From the Buffalo General Hospital and the University of Buffalo Medical School. This work was aided by a grant from the Junior Board of the Buffalo General Hospital. Received for publication, November 1, 1940.

†For the greater part of this work a preparation of bilirubin obtained from the Eastman Kodak Co., was used.

‡In a recent technical bulletin⁶ the use of a stock chloroform solution of bilirubin containing 50 mg. of bilirubin in 100 c.c. is recommended. No directions for preparing this solution are given. The reference furnished is to a paper of Malloy and Evelyn.⁵ In the original article the standard used contained 10 mg. of bilirubin dissolved in 100 c.c. of chloroform. We have not found any other reference to the use of chloroform solutions of bilirubin of this magnitude.

solve the bilirubin used to give concentrations as high as 400 mg. per 100 c.c. without the aid of heat; for the most part the stock solution used contained 250 mg. per 100 c.c.

The problem of diazotizing such solutions was next investigated. In the first experiments the chloroform solution was diluted with methyl alcohol, ethyl alcohol, or acetone until a homogeneous mixture with the water diazo reagent of Thannhauser and Andersen⁷ was obtained. When high concentrations of bilirubin were present, this method was satisfactory, but the amounts contained in chloroform extracts of serum gave colors which were so faint that quantitative measurement of them was difficult or impossible. Various attempts to obtain suitable colors with diazo reagents soluble in ethyl alcohol were unsuccessful, but finally a fairly satisfactory reagent was found. This solution was prepared as follows: 0.1 Gm. of sulfanilic acid was dissolved in 2 c.c. of concentrated hydrochloric acid and 4 c.c. of water. To obtain a satisfactory solution the mixture was heated upon a boiling water bath, and the small lumps of the acid were mashed with a glass rod. The concentrated acid solution was cooled and made up to 100 c.c. with absolute methyl alcohol. The preparation is a saturated solution of sulfanilic acid; some crystals separate on standing. The solution corresponds to solution A of van den Bergh. Solution B was prepared by dissolving 0.5 Gm. of sodium nitrite in 100 c.c. of methyl alcohol. Fifteen minutes before use 0.3 c.c. of solution B was added to 10 c.c. of solution A. Immediately before use one volume of the mixture was diluted with an equal volume of absolute methyl alcohol. The amount of water present in this solution is only slightly less than that which will cause a separation of water when added to chloroform, xylene, or benzene, and this renders the use of absolute alcohol in preparing the reagent necessary.

The diazo reaction was studied upon dilutions of the strong bilirubin solution already described. These dilutions were made with pure chloroform. The technique used for developing the color was as follows: To 2 c.c. of the chloroform solutions 1 c.c. of the diluted mixed diazo reagent was added and the solutions were mixed. After fifteen minutes the colors were read in a microcolorimeter. To ensure the presence of a maximum degree of acidity, and so uniformity of color, 1 c.c. of a strong (80 Gm. to 100 c.c.) solution of trichloroacetic acid in methyl alcohol was usually added just before the reading was made. As far as could be determined, however, this precaution was not necessary in the bilirubin solutions used as standards or in the chloroform blood extracts, for soluble buffer compounds were not present in concentrations great enough to affect the color. If fairly large amounts of a suitable buffer, such as ammonium acetate, were present, the color, which was normally a purple, had a marked reddish tint, and this source of error could be avoided or greatly lessened by the addition of trichloroacetic acid after diazotization.

The method could be successfully applied to solutions containing from 25 to 0.1 mg. of bilirubin per 100 c.c. of chloroform, i.e., in dilutions of the stock solution ranging from 1:10 to 1:300. When higher concentrations were present, the color obtained was too dark to be read in the colorimeter, and weaker solutions gave colors which were too faint to be measured accurately. Within the

range given the relationship between the color obtained and the amount of bilirubin present was linear, i.e., each solution read correctly when matched against those containing twice or one-half as much bilirubin.

Since the stock solution contained phenol, it was necessary to investigate the development of color when phenol solutions in chloroform were diazotized by the technique described. When such solutions contained 10 per cent of phenol, a greenish tint developed slowly. When 5 per cent or less phenol was present, no color could be observed when the method was carried out, nor could any measurable effect upon the weakest solutions of bilirubin studied be distinguished. Since the maximum phenol concentration in any of the solutions used was 1 per cent, there could have been no significant effect of phenol upon the results reported.

Although the actual amounts of phenol in the diazotized mixtures could not have measurably affected the colors obtained, it seemed possible that some reaction might occur between phenol and the bilirubin in the stock solution which would affect the color obtained upon diazotization. To exclude such a source of error, chloroform dilutions of the stock solution were made both soon after it had been freshly prepared and after it had been kept for months in the ice-box. These were diazotized simultaneously with solutions of bilirubin prepared in various ways. These control standards included very dilute solutions of bilirubin in pure cold chloroform, stronger chloroform standards prepared by the aid of heat, and solutions prepared by dissolving bilirubin in water containing minimum amounts of alkali. In the last instance the diazo procedure described above could not be used. These solutions were diluted with alcohol, and the chloroform-phenol solution was diluted with alcohol until the solution was miscible with water and the water-soluble diazo reagent of Thannhauser and Andersen could be used. Precautions were taken to insure the presence of equal concentrations of water, alcohol, and chloroform in the dilute solutions finally studied. No qualitative or quantitative differences in the color given by the reaction could be detected when bilirubin solutions prepared from the stock containing phenol were compared with bilirubin prepared in these three ways.

It seemed desirable to determine whether the colors given by different bilirubin preparations on diazotization were strictly comparable with each other. Many different lots of bilirubin obtained from the Eastman Kodak Co. gave identical results when treated by the technique outlined. A specimen of bilirubin from the Wilson Co., which had a somewhat different consistency from that used in most of the study, and one imported from Germany marked "Bilirubin Homberg," manufactured by Chemische Pharmazeutische A. G. Bad Homburg according to the directions of von Bergman and Eilboth, also gave colors which were the same qualitatively and quantitatively as those obtained from the bilirubin purchased from the Eastman Kodak Co.

The length of time during which the standard would not deteriorate under ordinary working conditions was investigated. The stock solution decomposed rapidly in direct sunlight, but even in clear glass the solution kept its strength for about six months when exposed daily for two or three hours to diffused daylight and artificial light in the laboratory if placed in a cupboard or icebox.

when not in use. A slight darkening of the initial light yellow tint took place, but the intensity of the color obtained upon treatment with diazo reagents remained unaltered. This finding was confirmed repeatedly with stock solutions of various concentrations. The test used was to compare the color obtained from the old bilirubin standard with that given by one weighed and dissolved immediately before use.

Besides these experiments with chloroform solutions of bilirubin, the diazo reaction described was carried out in various other solvents. In aqueous preparations the method was not satisfactory, but in various organic solvents only minor difficulties were encountered. When the stock solution of bilirubin in chloroform and phenol was diluted with benzene, xylene, acetone, ether, or carbon tetrachloride, the results were practically identical with those obtained when chloroform was used. The colors were not qualitatively the same in all the solvents, but in each solvent the colors were alike and were strictly proportional to the amount of bilirubin present. The lowest concentration which gave a visible color varied somewhat in the different experiments. With acetone, for example, the color given by a concentration of 0.04 mg. per 100 c.c. could just be distinguished, while benzene gave a slight color in solutions one-half as concentrated. All the solvents were fairly satisfactory when the concentration of bilirubin was 25 mg. per 100 c.c., although in some instances, notably benzene and carbon tetrachloride, the color given by such concentrations was very intense.

Results with absolute ethyl, methyl and butyl alcohol were less satisfactory. Precipitation took place in the higher concentrations with the first two solvents named, and in the butyl alcohol solution the bilirubin showed a marked tendency to separate on the glass of the container. In the range in which bilirubin was soluble the diazotization was satisfactory. The lowest visible color when dilutions were made with butyl alcohol was 0.08 mg. per 100 c.c. The methyl alcohol diazo reagent possessed no advantage over reagents prepared in water when the bilirubin was dissolved in solvents easily miscible with water.

Certain experiments were carried out on the diazotization of bilirubin extracted by chloroform. Bilirubin was dissolved in water containing a minimum amount of alkali and the pigment was extracted with chloroform after acidifying with hydrochloric and acetic acids. When an aliquot of such extracts was diazotized as described, the recovery ranged from 95 to 100 per cent of the theoretical values. Solutions prepared by diluting the stock solution in chloroform and phenol were used as standards in these experiments.

Freshly prepared solutions of bilirubin in alkali were added to serum. After acidifying and extracting with chloroform, the extract was diazotized as described. The recovery ranged from 90 to 95 per cent of the amount added. When normal human serum was acidified and extracted with chloroform, the amount recovered gave colors in some instances which corresponded approximately with those expected if the serum had contained 0.05 mg. of bilirubin per 100 c.c. Approximate measurements of the yellow color, of such an extract by the method of Soffer³ indicated the presence of a higher concentration of bilirubin than did the diazo color. The results suggested that yellow

pigments which were soluble in chloroform and were not diazotized were present in serum. No indication of the presence of a chloroform-soluble diazotizable compound other than bilirubin was obtained. When serum from patients with a marked degree of jaundice was extracted with chloroform, identical results were obtained, within the limits of accuracy of the methods, by the diazo technique and by measurement of the yellow color.

SUMMARY

Solutions containing as much as 400 mg. of bilirubin per 100 c.c. can be prepared by dissolving the pigment in a solution of chloroform containing 10 per cent phenol. Solutions of bilirubin in organic solvents containing phenol are more stable than in pure organic solvents. Phenol, unless present in high concentrations, has no effect upon the color given by bilirubin treated with diazo reagents. Diazotization of bilirubin dissolved in various organic solvents can be successfully accomplished by the use of a diazotizing solution prepared in methyl alcohol.

THE FORMOL-GEL REACTION*

DESCRIPTION OF A MODIFIED METHOD FOR QUANTITATIVE ESTIMATION OF SERUM GLOBULIN IN HYPERGLOBULINEMIA AND A CRITICAL ANALYSIS OF THE REACTION

FERNANDO BIGURIA, M.D., AND SAWYER FOSTER, M.D.
BOSTON, MASS.

INTRODUCTION

THE formol-gel reaction, first described by Gaté and Papacostas,¹ is a test for hyperglobulinemia regardless of the cause. It is performed by adding 2 drops of approximately 40 per cent formaldehyde solution to 1.0 c.c. of blood serum. Either solid gelification (Gaté-Papacostas test), or an increase in opacity (Napier's test)^{2,7} occurs in a "positive" reaction after a period of twenty-four hours' standing at room temperature. For a thorough treatment of the development of this test and its modifications, the work of Bing⁸ is recommended.

Wise and Gutman⁹ studied the formol-gel reaction in 113 sera with simultaneous chemical determinations of the several protein fractions. According to their criteria, a test was considered positive when it showed either an *increase in viscosity* from 1+ to 4+, as measured by a change from oily flow to a solid gel, or an *increase in opacity* from 1+ to 4+, as measured by a change from faint haziness to complete opacity. Almost invariably a positive reaction occurred when the globulin level was 4.0 per cent or above, and a negative reaction occurred at globulin levels below 3.4 per cent. Sera containing 3.4 to 4.0 per cent globulin, however, did not give a positive test consistently.

De Vries¹⁰ disregarded the opacity type of reaction and studied 28 sera which showed solid gelification. He concluded that the reaction was usually negative when the globulin level was below 3.6 per cent, and positive when above 3.7 per cent. He also noted that when sera were diluted with isotonic saline below globulin levels of 3.6 per cent gelification no longer took place.

The role of albumin in the formol-gel reaction has been discussed by various workers,⁸⁻¹⁰ the consensus of opinion being that albumin plays a minimal part, if any, in the reaction. The most conclusive studies are those of Napier,³ who showed by precipitation reaction and dialysis that the formol-gel test is specific for globulin, and that albumin has no influence.

In the present study the viscosity of formaldehyde-treated sera was measured and correlated with gelification (maximum viscosity change) and with the concentration of serum globulin. A modification of the formol-gel reaction is described for the quantitative estimation of serum globulin in hyperglobulinemia. In addition, observations were made on the relation of opacity to the content of serum globulin.

*From the First and Third (Tufts) Medical Services, Boston City Hospital, and the Department of Medicine, Tufts College Medical School.

Aided by a grant from the Charlton Research Fund, Tufts College Medical School.

Received for publication, August 26, 1940.

METHODS

Serum was obtained from samples of venous blood allowed to clot, the samples being taken during the fasting state. The albumin-globulin separation was performed by a modification of Howe's method,¹¹ employing 22.5 per cent sodium sulfate at 37.5° C. All nitrogen determinations were made by the micro-Kjeldahl method.¹²

Samples of serum containing an elevated concentration of globulin were diluted progressively with saline and allowed to stand at room temperature for twenty-four hours. These mixtures showed progressive decrease in the apparent viscosity from gelification to unaltered viscosity. At one dilution of the formaldehyde-treated serum the air bubbles introduced by shaking the tube did not rise to the surface but remained stationary. Since this phenomenon appeared consistently and was readily detected, it was arbitrarily chosen as the end point ("stationary bubble" end point). Repeated observations revealed that the concentration of serum globulin which correlated with this end point was 3.1 Gm. per cent. It was also noted that when air bubbles rose very slowly in a mixture, the globulin level was between 2.9 and 3.1 Gm. per cent.

The *modified formol-gel reaction* was performed by introducing serum into test tubes of 8 mm. bore in the following amounts: 1.0 c.c., 0.96 c.c., 0.92 c.c. etc., diminishing the quantity of serum in each subsequent tube by 0.04 c.c. Enough saline was added to each tube to make the contents up to 1.0 c.c. After mixing, 2 drops of approximately 40 per cent formaldehyde solution (U.S.P.) were added. The tubes were tightly stoppered, shaken, and allowed to stand at laboratory temperature for twenty-four hours. The tube demonstrating the above-mentioned "stationary bubble" end point was then selected, and the globulin content, in grams per 100 c.c. of serum, was calculated by the following formula:

$$\text{Grams per cent globulin} = \frac{3.1}{y}$$

where y equals the fraction of 1.0 c.c. of serum present in the tube showing the end point.

Example: If the "stationary bubble" end point occurred in the tube containing 0.80 c.c. of serum, the calculated globulin con-

$$\text{centration} = \frac{3.1}{0.80} = 3.87 \text{ Gm. per cent.}$$

The opacity of formaldehyde-treated sera was compared after twenty-four hours with corresponding untreated samples. The degree of opacity change was read according to the criteria of Wise and Gutnam.⁹

Direct observations of the viscosity (relative to water = 1) of fresh horse sera, treated as in the modified formol-gel reaction, were made by measuring the rate of flow in an Ostwald pipette¹³ at a temperature of 25° C. Similar observations were made also on corresponding dilutions of untreated sera.

RESULTS

1. *Direct Viscosity Studies on Horse Sera.*—Fig. 1 represents the direct measurements of viscosity made on three horse sera.* The apparent globulin

*Horse serum was used because of its high concentration of globulin, and because large amounts of serum are required for the Ostwald pipette.

content of the various mixtures was calculated from the formula using the "stationary bubble" end point. The mixture at this end point was too viscid to flow through the Ostwald pipette. The highest concentration of globulin in which the viscosity could be measured corresponded to a calculated value of 2.85 Gm. per cent. Analysis of the viscosity curve of the formaldehyde-treated sera shows that as the globulin content increased from 0.0 to 2.5 Gm. per cent, the viscosity rose slowly from 1.0 to 6.5; as the globulin content increased from 2.5 to 2.85 Gm. per cent, there was a remarkable rise in viscosity from 6.5 to 21.8. On the other hand, analysis of the viscosity of corresponding dilutions of untreated sera showed that as the globulin increased from 0.0 to 2.85 Gm. per cent, the viscosity rose only from 1.0 to 1.7.

Fig 1.—Direct measurements of viscosity on three horse sera twenty-four hours after the addition of formaldehyde.

The "stationary bubble" end point apparently corresponded to a definite but not measurable viscosity value, since diluted samples in which the viscosity could be measured followed a constant type of curve.

2. *Application of the Modified Formol-Gel Reaction.*—Eighteen human sera and one horse serum (Table I) showing the "stationary bubble" end point (or changes close to the end point) were studied using the modified formol-gel reaction. By application of the formula it was possible to calculate the apparent globulin content of 13 of these sera. In the other 6 sera in which the end point was not obtained, the globulin was estimated to be 2.9 or 3.0 Gm. per cent (see Methods). The globulin values obtained by the modified formol-gel reaction are compared with those obtained by the Howe method. The differences varied from 0.01 to 0.57 Gm. per cent, with an average of 0.22 Gm. per cent for all cases.

*Opacity readings were difficult in Cases 8 and 9, due to high cholesterol values.
a Represents determinations repeated on the same patient.

In this series the modified formol-gel reaction was used for estimation of globulin in hyperglobulinemia, with an average difference of 0.22 Gm. per cent globulin compared to values obtained by the Howe method. This error is similar to that of the Howe method itself.

3. *Relation of Opacity to Hyperglobulinemia.*—Fifteen sera (Table II) were studied which did not show the "stationary bubble" end point, but did show various degrees of opacity after the usual procedure with formaldehyde. By the Howe method the globulin content of these sera ranged from normal values to moderate elevations. Each of these sera showed some degree of opacity (1+ to 3+) which apparently bore no constant relation to its globulin content.

It may, therefore, be concluded that since opacity changes in formaldehyde-treated specimens are present in sera obtained from individuals with normal globulin values, opacity cannot be regarded as a reliable index of hyperglobulinemia.

DISCUSSION

A modified formol-gel reaction is described for estimating the globulin content of sera in hyperglobulinemia. This method has a decided advantage over the standard formol-gel reaction which can only be used as a qualitative indication of hyperglobulinemia.

The "stationary bubble" end point used in this modified technique has been standardized against the Howe method for globulin determination. Howe's method, however, has definite limitations inasmuch as the usual salting-out procedures produce incomplete separation of the albumin and globulin fractions.^{14, 15} The method devised by Tiselius¹⁶ precludes this source of error. Hence, its use in the standardization of the "stationary bubble" end point should result in further accuracy of the modified formol-gel reaction.

The close relationship between the degree of viscosity and the calculated globulin content strongly suggests that viscosity measurements may be used for estimation of globulin.

We gratefully acknowledge the assistance we have received from the following members of the Thorndike Memorial Laboratory: Miss Margaret A. Adams, for the chemical studies on proteins; Miss Constance Brooks, for the viscosity experiments; and Drs. T. H. Ham, W. T. Salter, and F. H. L. Taylor, for their interest and valuable suggestions and criticisms.

METHOD FOR THE QUANTITATIVE ESTIMATION OF ACETONE AND ACETOACETIC ACID IN URINE*

PRELIMINARY REPORT

LORRAINE F. NOYES, B.S., EAST PROVIDENCE, R. I.

THOUGH a number of methods for the quantitative determination of ketone bodies have been developed,¹⁻⁷ most of them are too time-consuming and laborious to justify their routine use in the average clinical laboratory. A definite need exists for a simple quantitative method of determining acetone and acetoacetic acid with ketoses due to diet or disease. To meet partially the need for a quantitative method for measuring ketone bodies in patients receiving ketogenic diets, Osterberg and Helmholtz⁸ modified a qualitative method for acetone and acetoacetic acid which allows a roughly quantitative estimation of beta-hydroxybutyric acid. The present report describes a method truly quantitative in its range, requiring no distillation or time-consuming gravimetric procedure, and for which the reagents are readily available. It has been used successfully in the laboratory of the Emma Pendleton Bradley Home for over a year.

THEORETICAL BASIS

This method is based on the Baeyer and Drewsen⁹ synthesis of indigo. Acetone and ortho-nitrobenzaldehyde, in the presence of sodium or potassium hydroxide, condense to give indigo. As an early means for the synthetic production of indigo this reaction was found to be nearly quantitative. By extracting the indigo produced with chloroform, the condensation may be adapted to the quantitative estimation of acetone and acetoacetic acid as acetone when these are present to a pathologic degree in urine.

Reaction:

*From the Emma Pendleton Bradley Home, East Providence.
Received for publication, August 2, 1940.

While the reaction is quantitative when large amounts of acetone and ortho-nitrobenzaldehyde are present, it is not quantitative when only small amounts of acetone are present. However, the amount of indigo formed is proportionate to the acetone present and to the time of standing. Natural standards must be used, made up at the same time as the unknown, and from acetone solutions of low concentration. Indigo is only slightly soluble in chloroform, so that care must be taken when large amounts of indigo are formed that the dye is completely extracted. Several extractions may be necessary when acetone and acetoacetic acid are present in large quantities.

Too great an excess of ortho-nitrobenzaldehyde or alkali or both will cause secondary reactions, so that the chloroform extract will be greenish and useless for comparison. The solution of indigo in chloroform remains stable for several hours and, if the concentration of indigo is not too great, for several days. Acetaldehyde and pyruvic acid also condense with ortho-nitrobenzaldehyde to give indigo. However, acetaldehyde is never present in urine, and as the method is only useful in the pathologic range, the amount of pyruvic acid present at any time is so small that the error thus introduced is negligible. Other substances present in normal or pathologic urines have not interfered with the reaction either by reacting with the reagents or by preventing the reaction. A review of the literature and practical experience indicate that the condensation is specific for acetone, acetaldehyde, and pyruvic acid.

METHOD

Reagents.—Five per cent solution of ortho-nitrobenzaldehyde* in 95 per cent ethyl alcohol.

Ten per cent potassium hydroxide.

Solutions.—Solutions of acetone containing 1.0 and 0.5 mg. of acetone per cubic centimeter should be made up and accurately titrated with iodine. Standards for urines giving a faintly positive test for acetone and acetoacetic acid should be made from 1 or 2 c.c. of the 0.5 mg. per cubic centimeter of standard, and for those giving a strongly positive test from the 1.0 mg. per cubic centimeter of standard.

Procedure.—Twenty cubic centimeters of a urine giving a positive test for acetone or acetoacetic acid are transferred to a large test tube fitted with a delivery tube. Fresh cork stoppers or rubber stoppers covered with tin foil must be used. The delivery tube need not be cooled during the time the specimen is in the water bath. The tip of the delivery tube is placed well below the surface of 4 c.c. of distilled water in a small test tube. The sample is immersed in the boiling water bath for ten minutes to precipitate proteins and to convert the

*The ortho-nitrobenzaldehyde was secured from the Eastman Chemical Co.

acetoacetic acid to acetone. The boiling of the water bath is so adjusted that very little vapor is transferred to the receiver. The sample is then cooled to room temperature. The receiver and the delivery tube are rinsed with small portions of distilled water and the washings are added to the sample, which is then measured and filtered.

TABLE I

RECOVERY OF ACETONE AND ACETOACETIC ACID FROM URINE BY NEW METHOD

All urines are those of children between the ages of 6 and 12 years. The results are expressed as milligrams of acetone per 100 c.c. of urine

Diet 3:1	--	--	--	--	--	--
Ketogenic urine	--	113.61	118.43	--	--	--
Diet 4:1	--	--	--	--	--	--
Diabetic urine	--	23.11	22.86	10.00	9.92	9.76
Diabetic urine	--	3.29	3.16	10.00	9.67	9.52

A volume of filtrate equivalent to 10 cubic centimeters of urine is transferred to a large test tube. One cubic centimeter of the 5 per cent alcoholic solution of ortho-nitrobenzaldehyde and 2 c.c. of 10 per cent potassium hydroxide are added to the unknown. It is essential that the reagents be added in this order to prevent the precipitation of the ortho-nitrobenzaldehyde. The unknown and a standard, which is set up at the same time and with the same quantity of reagents, are allowed to stand for one hour. The indigo is then extracted with chloroform. Three cubic centimeters of chloroform are sufficient to extract the indigo when the acetone concentration is low. When much indigo is present, it may be necessary to make several extractions. A separatory funnel is used for the extraction and the extraction will be faster if warm water is added to the unknown. Where the tap water is relatively pure it may be used. The extract is transferred to a calibrated tube containing 2 c.c. of water. By the addition of chloroform, the standard and the unknown are adjusted to approximately the same indigo concentration. Cloudiness of the chloroform extract, often present after standing, may be removed by warming the solution under tap water. Indigo is calculated as acetone per cubic centimeter of chloroform in the standard. Standard and unknown are then compared in the colorimeter.

$$\frac{RS}{RU} \times A = \frac{B \times C \times V}{v} = \text{milligrams of acetone plus acetoacetic acid as acetone in the total specimen.}$$

RS is the reading of the standard, usually 20; RU is the reading of the unknown; A is the milligrams of acetone per cubic centimeter of chloroform of the standard; B is the milligrams of acetone per cubic centimeter of chloroform of the unknown; C is the number of cubic centimeters of chloroform of the unknown; V equals the total volume of the specimen; v equals the volume of the sample.

DISCUSSION

In the upper range of total ketone bodies (over 0.2 per cent) the method was found to be truly quantitative. In the lower range the results were low. It seems probable on the basis of further studies now in progress that the range of this method may be increased and that it may be modified to measure total ketone bodies.

SUMMARY

1. A practical clinical method is presented for the quantitative estimation of acetone and acetoacetic acid in urine.
2. The method is based on the condensation of acetone and ortho-nitro-benzaldehyde in the presence of sodium or potassium hydroxide to give indigo.
3. The method is simple and accurate for the estimation of acetone and acetoacetic acid when these substances are present in the urine to a pathologic degree.

A RAPID METHOD FOR THE ESTIMATION OF URINE SUGAR*

MICHAEL SOMOGYI, PH.D., ST. LOUIS, MO.

THE most satisfactory clinical approach for studying the carbohydrate utilization (tolerance) of diabetic patients is the one employed by Naunyn and his school at the turn of the century. Essentially it consists in preparing daily balance sheets of carbohydrate consumption and loss of glucose in the urine, the balance representing the amount of carbohydrate utilized in twenty-four hours.

In clinical and laboratory investigations during the past six years we have used this procedure routinely. In cases in which insulin therapy was applied, we did not stop at estimating the total glucose output for twenty-four-hour periods, but found it necessary to run separate quantitative determinations on every batch of urine collected between insulin injections; the information thus obtained proved to be the best criterion for the adequacy of the insulin dosage. One of the advantages of this procedure is that it can be pursued for any length of time without hardship to the patient, whereas gathering of the equivalent information by serial blood sugar determinations is scarcely tolerable for days and nights in a row.

The large number of sugar determinations in our laboratory (150 to 200 on some days) was feasible only with the aid of a rapid and simple method. We describe herein a procedure that we have been using during the past five years. It requires no more time and skill than a properly performed qualitative test.

The basis of our method is the well-known change of color which takes place when sugars are heated in alkaline solution; the shade which develops in the reaction varies from pale yellow to dark amber, depending upon the concentration of sugar. Our primary task was to devise experimental conditions under which the colors developed would be in the closest possible proportionality to the concentration of the sugar. As additional conditions we stipulated a reasonably short reaction period and sufficient sensitivity to permit the estimation of glucose over a wide range of concentrations.

Without enlarging on details of the exploratory experiments, let it be stated in brief that sodium carbonate as the alkali proved to satisfy the requirements. Glucose quantities varying from 1 to 30 mg. in 5 to 6 c.c. of reaction mixture yielded maximum color intensities when the concentration of the carbonate varied within the wide range of 8 to 15 per cent. The maximum color appeared after heating alkaline glucose solutions in a boiling water bath for seven minutes; prolongation of the heating beyond ten minutes caused a gradual fading of the color. (Boiling over an open flame for one and one-half to two minutes produces

*From the Laboratory of the Jewish Hospital, St. Louis.
Received for publication, November 29, 1940.

the same colors as heating in the water bath for seven to ten minutes.) In the procedure based upon these facts the following reagents and equipment are required:

Reagents.—

1. A 10 per cent solution of anhydrous sodium carbonate.
2. A series of standard glucose solutions, ranging in concentration from 0.5 to 6 per cent.

The standard glucose solutions are best prepared from a stock solution, a 10 per cent solution of glucose in water, saturated with benzoic acid (0.25 per cent) as a preservative. From the stock a series of 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, and 6.0 per cent standard solutions is prepared by dilution with water containing 0.25 per cent benzoic acid. Stock solution and standards keep indefinitely at room temperature.

Equipment.—

1. Test tubes of 14 mm. inside diameter. All test tubes employed must be of identical diameter. A simple way to select uniform test tubes is to measure accurately 10 or 15 c.c. portions of water into a series of tubes and to retain for use only those in which the water level is of the same height.
2. Pipettes for measuring 0.5 c.c. and 5.0 c.c. portions of fluid.

Procedure.—

Introduce into seven test tubes 0.5 c.c. portions of the standard glucose solutions, and into the other test tubes 0.5 c.c. portions of the urines to be analyzed, then add to every test tube 5 c.c. portions of the sodium carbonate reagent. Mix the contents, place the test tubes in a rack, and heat, immersed in boiling water, for eight minutes. Racks accommodating from one to two dozen (or more) test tubes are serviceable.

After eight minutes' heating read the results without undue delay. To this end place the standards in an ordinary test tube rack, leaving one space between each two tubes free for the matching of the test tubes containing the urine samples. When matching colors, view the test tubes transversely, holding the rack against a window or an artificial source of light. If the color of the unknown does not closely match any one of the standards, but lies between two of them, estimate the intermediate value by interpolation. If, for example, the color shade of an unknown is halfway between the 3.0 and 4.0 per cent standards, its sugar content is 3.5 per cent; if it is between 3.0 and 4.0 per cent, but distinctly nearer the 3.0 per cent standard, then it contains from 3.2 to 3.3 per cent of glucose, etc.

In laboratories where urine sugars are determined throughout the day, the slow but measurable fading of the colors at room temperature constitutes a drawback. One can get along with standards prepared once a day, but with the realization of the fact that analyses performed when the standards are several hours old will give readings that are 10 to 15 per cent too high. This is especially true on hot summer days, when the fading of colors is accelerated by high room temperatures.

Such degree of accuracy seems quite acceptable for a semiquantitative method; but we succeeded in eliminating this source of error by devising permanent standards, in sealed test tubes, which remain unchanged indefinitely. After an extensive search for adequate permanent standards, alcoholic iodine solutions were finally found best suited for the purpose; Dr. Simon Russi and other workers in our laboratory gave valuable assistance in this endeavor.

The stock solution for permanent standards is a 0.01 normal iodine solution in absolute alcohol from which a series of solutions is prepared by dilution with absolute alcohol. The normality of the several diluted solutions is given in Table I. A 0.008 normal alcoholic iodine solution is of the same color, shade, and intensity as the 6 per cent glucose standard and thus takes the place of it; a 0.0058 normal iodine solution is a substitute for a 5 per cent glucose standard, and so on, as given in Table I.

TABLE I
CONCENTRATIONS OF ALCOHOLIC IODINE SOLUTIONS USED AS PERMANENT STANDARDS

NORMALITY OF IODINE SOLUTIONS	CORRESPONDING PERCENTUAL GLUCOSE CONCENTRATIONS
0.0004	0.5
0.0009	1.0
0.0018	2.0
0.0028	3.0
0.0043	4.0
0.0058	5.0
0.0080	6.0

TABLE II
COMPARISON OF RESULTS OF URINARY SUGAR DETERMINATIONS BY THE NEW METHOD, WITH TRUE SUGAR VALUES ESTIMATED BY A COPPER-iodOMETRIC METHOD

NO.	GM. OF SUGAR PER 100 C.C. OF URINE	NEW METHOD
	COPPER-iodOMETRIC METHOD, WITH STAFFER-SOMOGYI REAGENT NO. 50	
1	0.21	0
2	0.42	0.3
3	0.31	0.5
4	0.41	0.3
5	1.2	1.2
6	1.3	1.3
7	2.1	2.0
8	2.6	2.5
9	3.0	3.0
10	3.9	4.0
11	5.0	5.0
12	5.0	5.0

Approximately 5 c.c. portions of these iodine solutions are introduced into pyrex test tubes of 14 mm. inside bore and the tubes are then sealed. In this condition the standards remain unchanged without requiring any special precautions, as for example, protection from light or changes in room temperatures. The permanence can be readily ascertained by comparison with standards freshly prepared with pure glucose solutions. The earliest permanent standards in our laboratory are now over two years old and show no deterioration.

When using the permanent standards with a rather simple comparator block,* the accuracy of the method is great enough to advance it into the rank

*Sets of permanent standards with a matching block were placed on the market by A. S. Aloe Co., St. Louis, Mo., and are available through laboratory supply houses.

of adequate quantitative methods. The accuracy of this procedure is illustrated in Table II, in which results obtained by it are compared with determinations run by the copper-iodometric reagent of Shaffer and Somogyi.¹ It is to be remarked that the results of the copper-iodometric analysis represent true (fermentable) sugar values, that is to say, values that do not include any reducing matter other than sugar. These values, as may be seen, compare favorably with those obtained by the new procedure.

The method, we reiterate, is as rapid and simple as a properly executed qualitative test for urinary sugar, particularly when one is to carry out considerable numbers of determinations. In instances where only occasional single determinations are made, however, preliminary heating of a water bath to boiling and heating of the reaction mixture for eight minutes may involve a waste of time. This difficulty can be overcome by the use of an open flame. The analysis then is carried out as follows:

Measure into a test tube 0.5 c.c. of urine and 5 c.c. of the carbonate reagent, drop in two small glass beads or quartz pebbles, and a drop of paraffin oil (or a corresponding bit of paraffin wax), heat to boiling over an open flame and, turning the flame low, keep the liquid *very gently* boiling for one and one-half to two minutes. The color develops to the same shade as after heating for eight minutes in a boiling water bath and can be matched against the permanent standards.

Since this method consumes no more time and work and requires no more skill than the generally employed qualitative methods, as for example Benedict's, in our institution the quantitative estimation of urine sugar has completely displaced the qualitative tests based upon copper reducing power.

A distinct advantage of the carbonate reaction is that it is more specific for sugars than are copper reagents. This quality comes mainly into play when dealing with concentrated urines, so frequent in hot summer weather, which may reduce appreciable amounts of copper without containing any abnormal amounts of glucose; with our method such urines give negative results.

If the urine is abnormally dark colored or contains blood or bile, it must be decolorized preliminary to the analysis. To this end about 2 to 3 Gm. (roughly one-half teaspoonful) of Lloyd's reagent is added to about 10 c.c. of urine in a test tube or a small flask, the mixture is gently agitated for about a minute (or longer) and then filtered through a dry filter paper. The nearly colorless filtrate is ready for analysis.

MEDICAL ILLUSTRATION

LANTERN SLIDES: A NEW TECHNIQUE*

M. MUSCHAT, M.D., F.A.C.S., PHILADELPHIA, PA.

THE use of lantern slides in medical presentations is becoming more and more popular. The success of a presentation, whether long or short, depends largely upon the number and excellence of the slides shown. To the essayist it means a very definite aid in expounding and elucidating the details and fine points of the presentation. The audience is instantly aware and attentive, and remembers well the important part of the subject under discussion.

Our present-day photographic method of preparation of slides is rather uniform. Charts, graphs, tables, and drawings are photographed and positive slides are made. This method is good, but its cost is high and forces the average essayist to limit the number of slides he uses. By thus limiting himself to only a few slides he foregoes the opportunity of stressing many convincing points, leaving the impression of haste and incompleteness.

An additional method is with the use of cellophane, which is available as "announcement sheets" and "radio mats." The cellophane, encased in an envelope, is covered with a sheet of carbon paper. After the material is copied on the typewriter, the envelope is opened, the carbon copy is removed, and the finished film is placed between two cover glasses and taped. This method is simple and inexpensive, but it can only be used for writing a few sentences on a small area. Previous attempts to make charts or drawings on cellophane have ended in failure because of the small area (7.6 by 5.7 cm.) available, the smeary copy, and the inability to erase errors.

I am presenting here a novel method of slide preparation that is easy to handle and is low in cost. It consists of a very thin frosted paperlike film, upon which one can typewrite, draw with a pencil or pen and India ink, and even use water colors with good results. This material can be handled without difficulty, for it keeps its shape and does not become smeary. It possesses all the qualities and characteristics of a fine drawing or tracing paper. After the drawing or typing is completed, the frosted sheet is placed between two glass slides, bound with tape, and is ready for use. Thus an original drawing or chart can be prepared without having to resort to photography.

Material Used.—The frosted film is available on the market as "Traceolene" (light weight only), "Frosted Protectoids" (three weights or thicknesses:

*From the Departments of Urologic Surgery, Mount Sinai Hospital and the Medical School of the University of Pennsylvania, Philadelphia.

Received for publication, January 21, 1941.

light, medium and heavy), and "Plastacele" (varied thicknesses). In testing various thicknesses their optimum usefulness for specific purposes was found. The results of this study are summarized in Table I.

Typewriting.—The frosted film, cut into strips of 9.2 cm width, is placed in the typewriter. The typing is done on the frosted side. It is better to use a few sheets of ordinary paper behind it, to obtain a sharper print. An extra black ribbon will produce darker print and show up better on the screen. The best print is obtained by placing the film in a folded carbon paper, thus obtaining a double print: front and back. One can utilize the entire surface area of the frosted film, leaving a margin of about 2 to 3 mm. for the binding tape (Fig. 1). The surface area thus available is 55 per cent greater than in the commercial cellophane method marketed as "radio mats." This ratio is shown in Fig. 2.

TABLE I

	LEAD AND CARBON PENCILS	INK	INDIA INK	STAMP	TYPE	PENCIL ERASURES	INDIA INK REMOVAL BY SCRATCH- ING	CLARITY OF TYPE	HAN- DLING
Cellophano Tracelene or frosted: 88 AB	None Poor	Poor Poor	Poor Good	Poor Fair	Fair Good	None Good	Poor Fair	Smeary Clear	Smeary Clean
Frosted: 150 AB	Good	Poor	Good	Fair	Good	Good	Good	Clear	Clean
Frosted: 300 AB	Poor	Poor	Good	Poor	Poor	Good	Good	Clear	Clean

Some projectors and lantern slide carriers are so constructed that they cut in on the sides of lantern slides in which the data extend too far to the right or left. It is advisable, therefore, to have the contents of the slide cover a space of only 7 cm. vertically and 7.5 cm. horizontally. This allows a space on the left of the image for attachment of a label or tab on which are noted the necessary data as to the owner, the nature of the contents, and the number of the slide. The large circle in the lower left-hand corner is an indicator for the projectionist to put the slide in the machine in the proper manner.

When a comparison is made of the print on clear cellophane with that on frosted film, the sharpness of the letter print in the frosted material and the smeary, unclean result on the cellophane can readily be seen. An enlargement of both results illustrates this difference in Fig. 3.

Plain rubber stamping can also be used, as seen in Fig. 4.

If partial legends are required, they should be printed with the proper spacing. The frosted paper is then cut to the correct sizes and placed on the drawing or directly on the slide as needed.

Drawing With Pencil.—In drawing an object on frosted film the same method is employed as when using ordinary paper. I recommend the use of carbon pencils since the marks left by these pencils will show up better on the screen. By using shaders dipped in carbon pencil dust on a sandpaper board, I was able to draw the most delicate shadings desired. Shaders are made by

Fig. 5.

cutting and sandpapering to a point ordinary erasers and pieces of cork. A sharp, pointed pencil may be used on this frosted material without tearing or wrinkling. The film will stand erasing with hard and soft rubber (Fig. 5).

Fig. 6.

Fig. 7.

Drawing With India Ink.—The finest lines can be drawn on frosted film with pen and India ink. I drew charts and graphs on it the same as I do on fine drawing paper. Brilliant results may be achieved. Scratching out of the ink is easy. Ink smears on the glazed back may be wiped off with a wet sponge (Fig. 6).

Shading of Areas.—For this work I have utilized a special cellophane film with various designs or patterns of dots and lines printed on it. It is called "Transograph Shading Film"—A. Standard nonadhesive, and B. Contak adhesive back (see Fig. 7). Spaces and columns were shaded by pasting them on the frosted film.

Fig. 8.

Fig. 9.

The shading film is useful in many ways. When using the Contak with the adhesive back, one side of the film is covered with a white paper upon which one

can draw with pencil or ink. After the required area is marked off, it is cut out. The protective white paper is then lifted off and the pattern is pasted directly on the frosted film. In order to produce varied shadings, the same film is pasted on the first layer of film, with the design running in a different direction. Many different types of shadings can thus be obtained. The handling is very simple and clean, and the final effect on the screen is brilliant (Figs. 8 and 9).

Tracings.—The frosted film is adaptable as a tracing paper in making a tracing of any desired image. By placing it upon the picture and fixing it with Scotch cellulose tape, one can trace any minute detail, either with carbon pencil or India ink. Such tracings can be very useful to those who cannot do freehand drawing.

Fig. 10.

Color Slides.—Many desired effects in flat color can be obtained by the use of colored cellophane. The cut-to-shape colored cellophane, pasted on the frosted film, produces an effective color on the screen for differentiation. It can be pasted on the adhesive side of adherent cellophane, thus fixing it in permanent position. Colored cellophane is used for square and round graphs.

Permanency.—Slides made of frosted film are superior to thin cellophane in maintaining their shape and clarity over a long period of time. Under ordinary conditions they will not warp or wrinkle, and the type will not fade.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILBUFFE, M.D., ABSTRACT EDITOR

SERUM LIPASE, Diagnostic Significance of Determinations of, Johnson, T. A., and Bockus, H. L. Arch. Int. Med. 66: 62, 1940.

This report comprises data on 616 independent determinations of serum lipase for 371 patients, performed over a period of three years. In the authors' experience, values for serum lipase are significant when they exceed 1 e.c. of a twentieth-normal solution of sodium hydroxide.

A large number of patients with functional and organic disorders, but with no clinical, surgical, or pathologic evidence of pancreatic disease were examined in order to determine the incidence of positive tests in nonpancreatic disorders. Uniformly normal lipase values were obtained in uncomplicated diabetes mellitus, hyperthyroidism, syphilis, tuberculosis, hypothyroidism, venereal lymphogranuloma, nonpancreatic malignant disease, uncomplicated peptic ulcer, gastritis, gastroduodenitis, functional colonopathies, nonobstructive organic diseases of the small and large intestines, and heart disease. The significance of normal values for lipase in these conditions is emphasized in order to stress the specificity of the test as an indication of pancreatic disease.

The study confirms the reports of others that diseases of the pancreas show the highest incidence of increased values for serum lipase. In 9 of 11 patients with acute pancreatitis and in 5 of 8 patients with proved cancer of the pancreas, pathologic values for lipase were obtained. Further proof that disease of the pancreas is the usual cause of elevations in serum lipase is supplied by the data for a group of 60 persons with cholelithiasis. A positive test was obtained in only 1 of 31 patients without jaundice and without a previous history of jaundice, whereas in 31 per cent of the remaining 29 patients with cholelithiasis with jaundice or with a history of jaundice values above 1.0 e.c. were obtained.

The study does not supply any support for the view that hepatocellular injury causes an elevation of the serum lipase. Normal values were obtained in 15 persons with so-called catarrhal jaundice, 2 with toxic or infectious hepatitis, and 12 with hyperthyroidism. These findings tend to throw some doubt on the theory that hepatic dysfunction may disturb the level of the serum lipase. If the findings in cases of catarrhal jaundice are confirmed by others, the lipase test may prove to be of distinct value in certain cases of jaundice of obscure causation, for an elevated value for serum lipase would tend to exclude the diagnosis of catarrhal jaundice.

As might have been anticipated, the authors noted no relation between hyperbilirubinemia and the values for serum lipase. This statement is based on simultaneous determinations of serum lipase and bilirubin on the same blood samples from 44 jaundiced patients. The fact may be considered additional evidence against the theory of a hepatic causation for hyperlipasemia.

In chronic hepatic disease associated with widespread destruction of the hepatic parenchyma, there was a rather high incidence of hyperlipasemia. High values were obtained in 7 of 24 patients with cirrhosis of the liver and in 2 with hepatic tumor. An examination of the material (Table 4) does not supply very convincing evidence that the possibility of pancreatic involvement was satisfactorily eliminated. The pancreas was examined at autopsy in only one patient (9) and was reported to be normal.

Four patients with intestinal obstruction had elevated values for serum lipase. The authors have found no reports of a similar observation in the literature. If the observation is confirmed by others, the serum lipase test will have another clinical application of importance.

The authors feel that this study justifies the conclusion that the serum lipase determination is of considerable clinical importance and that a wider application is warranted than it now enjoys.

SEPTICEMIA, Staphylococcic, Sutherland, R. T. Arch. Int. Med. 66: 1, 1940.

The treatment of staphylococcic septicemia should not be considered hopeless, since by early active treatment the mortality can be reduced.

Patients having active or recently healed carbuncles, furuncles, or blisters, with either prolonged, mounting, or septic temperatures for which no cause can be found; patients with symptoms and signs of a beginning osteomyelitis; and patients with staphylococci in the blood, should immediately have heroic treatment.

At present there is no standard as to what constitutes such treatment.

Experience suggests that in addition to supportive and surgical care, early treatment with large doses of antitoxin in a total dosage, varying from 300,000 to 1,000,000 or more units, together with some bactericidal element such as immune blood, gives encouraging results.

SCHICK REACTION, Effect of Human Serum on the Blood Antitoxin Titer and, Barenberg, L. H., Greenstein, N. M., and Leighton, B. Am. J. Dis. Child. 60: 36, 1940.

Because of the fact that susceptibility of a person to diphtheria can be determined within twenty-four hours by means of the Schick test and blood titration, diphtheria was singled out from other contagious diseases for special study to determine the mechanism by which the routine injection of human serum prevents the development of secondary contagious diseases in a hospital ward.

This investigation is based on observations of the effect of human serum on the cutaneous reaction in 141 children with positive reactions to the Schick test and on the blood titer of 55 of this group. The children ranged in age from 6 months to 12 years. The Schick test was performed on every patient admitted to the hospital, and a retest was given within several days after the serum injection. Subsequent retests, at monthly intervals, were carried out on patients in whom a reversal of the reaction followed serum injection. Intramuscular injection of from 10 to 30 c.c. of human serum was given to every patient within twenty-four hours after admission. Within twenty-four hours after the serum injection a central pallor developed in the area of the Schick reaction, and within forty-eight hours there was a clear demarcation between the central pallor and the peripheral inflammatory zone. In patients to whom serum was not given, this phenomenon did not occur. This anomaly did not indicate that a subsequent reversal of the Schick reaction would take place.

Injection of human serum brought about a reversal of the Schick reaction in 98 children, or 69.6 per cent. In 43 children, or 29.4 per cent, the Schick reaction remained persistently positive despite the serum injection. The intensity of the Schick reaction, however, apparently was reduced by means of the human serum. The modification of the reaction of 8 children who received from 10 to 15 c.c. was similar to that of 24 children who received from 20 to 45 c.c. of serum.

Titration studies were done on 55 children. Of 33 children in whose Schick reaction the serum brought about a reversal there was a significant rise in titer in 91 per cent, while of 22 whose Schick reaction was persistently positive there was only a slight rise in titer in 40 per cent. There was a close correlation between the rise in serum titer and the reversal of the positive Schick reaction. Analysis is presented of the observations on 39 children of the youngest age group, in whom 22 whose Schick reaction became negative after injection of serum had a rise in titer of 166.6 per cent, as compared with a rise of 44.4 per cent in 17 children whose Schick reaction was persistently positive. The average titer of the donors' serum in the former group was 0.0047 unit per cubic centimeter higher than the amount of the serum given to the latter group. These observations would indicate that the higher

potency of the serum was responsible for the reversal of the Schick reaction as well as for the rise in titer of the patients' blood. In this study the repetition of the Schick test was not responsible for the rise in the blood titer or for the reversal of the reaction, as the interval between the second test and the subsequent titration ranged between seven and thirty-three hours, a period in which the Schick material could not be a factor.

Human serum protected more than half of the children for twenty and five-tenths weeks and the remainder for three and two-tenths weeks. The average period of protection was thirteen weeks in the cases of the youngest group of children, as compared with twenty-two and twenty-six weeks in those of the two older groups. It was found that the youngest age group, in which the smallest percentage was protected, lost its immunity sooner.

MONONUCLEOSIS, Infectious, The Histological Lesion in Lymph Nodes in, Gall, E. A., and Stout, H. A. Am. J. Path. 16: 95, 1940.

A survey of the literature reveals the fact that no consistent lesion has hitherto been described in the lymph nodes from patients with infectious mononucleosis. The authors have studied lymph nodes removed from ten such patients at various stages in the illness and have described a characteristic morphologic pattern. This appears with such regularity in this disease and so rarely in other conditions that it is believed to have diagnostic importance.

The basic lesion of infectious mononucleosis is apparently the result of the varied responses of several different elements composing the lymph node to a single, presumably irritative stimulus. The structures manifesting this reaction may be enumerated as follows: (a) lymphoid follicles, (b) lymphoid cords, (c) lymph sinuses, (d) sustentative elements and blood vessels.

The important crude diagnostic feature which serves in the differentiation from primary neoplastic disease of the lymph node is the retention of gross architectural relationships. This is particularly the case with reference to the persistence of subcapsular and radial sinuses.

The basic process underlying the lymph node lesion in this disease is essentially the result of proliferative stimulation of the components of the node.

In what appears to be the early stages of the lesion, the germinal centers of the lymph follicles become hyperplastic and show large secondary nodules. These consist of masses of apparently fused cells with abundant, poorly defined, basophilic cytoplasm and large vesicular nuclei (stem cells), and also of varied numbers of mononuclear elements with more sharply defined and demarcated eosinophilic cytoplasm and eccentrically placed lobulated or reniform nuclei (probably clasmatoocytes). Mitotic figures are numerous and there is evidence of phagocytic propensity among many of the clasmatoocytes.

At the same time there are increased numbers of mitotic figures in the larger cells of the extrafollicular lymphoid substance in both cortical and medullary regions.

During the florid stage of the disease the appearance of the lymph node is quite unusual and presumably specific. The node is enlarged and shows greatly increased cellularity in the medullary, cortical, and sinus substance. The cords are swollen by a rich mixture of small and large lymphocytes, stem cells, and lymphoblasts, infectious mononucleosis cells, and large eosinophilic phagocytic elements. Follicles persist in some cells, but in others they are apparent only as occasional, partially disrupted germinal center fragments, and reticulum stains exhibit a vestige of concentric perifollicular arrangement. There is marked sinus compression and distortion, although identity is preserved. The sinus lumina contain variable numbers of cells similar to those noted in the pulp. Cells of this type are also evident in small numbers in both the trabeculae and capsule of the node. There is an apparent increase in reticulum meshwork fibrils, vascular channels are much more abundant than usual, and vascular endothelium is hyperplastic.

BILIRUBIN, Comparison of Tests for, in Urine, Foord, A. G., and Baisinger, C. F. Am. J. Clin. Path. 10: 238, 1940.

In doing tests for bilirubin in the urine, particularly to avoid missing small quantities, some method of concentration of the pigment should be used, either precipitation and adsorption by barium chloride or adsorption by tale. The most commonly used tests on unconcentrated specimens are not sensitive and often are difficult to read.

The diazo spot method of Godfried is a highly satisfactory method, as are also the Harrison spot and the Naumann methods. The latter is perhaps more time-consuming. The red color developed in the diazo spot method is more easily read than the colors produced by the other methods.

Diazo Spot (Godfried).—Precipitate bilirubin with barium chloride, filter, spread filter paper on dry filter paper, and add 1 drop of diazo reagent, 4 drops of 95 per cent alcohol, and 1 drop of phosphate buffer. Red to pink color denotes a positive reaction. Test works best with small amounts of bilirubin. If precipitate is deep yellow in color, add more of reagents, or better, dilute urine and repeat. A quantitative technique by diazo method is given by this author.

Harrison Spot (Godfried).—Add to 10 c.c. urine 5 c.c. of 10 per cent barium chloride solution, mix and filter. Spread filter paper on dry filter paper. Add 1 to 2 drops of Fouchet's reagent (trichloroacetic acid 25 Gm., water 100 c.c., 10 per cent ferric chloride 10 c.c.). Blue to green color indicates a positive reaction.

Naumann.—Filter through paper in a Buchner funnel of 3.5 cm. diameter 5 c.c. of a 10 per cent emulsion of tale in water. Suck nearly dry. Add 5 c.c. of urine and suck nearly dry. Add 1 drop of Fouchet's reagent or 10 per cent nitric acid in middle of disk. Blue color is positive.

BONE MARROW, Sternal, in Hyperthyroid and Myxedematous States, Jones, R. M. Am. J. M. Sc. 200: 211, 1940.

Sternal marrow aspirated from 18 "normal" individuals contained an average of 6.2 per cent nucleated cells.

Sternal marrow from 12 individuals with hyperthyroidism contained an average of 13.5 per cent nucleated cells, about $2\frac{1}{2}$ (217 per cent) times the "normal" finding.

Sternal marrow from 7 individuals with hypothyroidism contained an average of 2.4 per cent nucleated cells, a little more than one-third (38 per cent) of the "normal" average.

Five patients with hypothyroidism treated with desiccated thyroid or thyroxin, and subsequently studied, showed a marked rise in the percentage of nucleated cells in the sternal marrow.

A patient with thyrotoxicosis following thyroid ingestion showed a marked decrease in the percentage of nucleated cells in the marrow when the thyroid was stopped. There was a less marked but definite decrease in patients where subtotal thyroidectomy was performed.

The hyperplasia found in the marrow of the hyperthyroid individuals was myeloid in character, and was not reflected in the peripheral blood.

SULFANILAMIDE, Effect of Sulfapyridine and, Upon the Blood Pigments of White Rats, Smith, P. K. Am. J. M. Sc. 200: 183, 1940.

In white rats that had received orally for one month daily doses of sulfanilamide, 760 mg. per kilogram, small, but significant, amounts of methemoglobin and somewhat larger amounts of sulfhemoglobin were found. By comparison with a group of control rats there was a decrease in total hemoglobin of about 10 per cent.

Under similar conditions a daily dose of sulfapyridine, 1,050 mg. per kilogram resulted in a similar amount of methemoglobin without an appreciable amount of sulfhemoglobin. There was no significant reduction in total hemoglobin.

PERNICIOUS ANEMIA, The Erythrocyte Response to Treatment, Riddle, M. C. Am. J. M. Sc. 200: 146, 1940.

From data in 523 patients with pernicious anemia satisfactorily treated, the average weekly increase in the erythrocyte count at the end of two weeks of treatment was found to bear an inverse relationship to the erythrocyte count before treatment.

This relationship is expressed in the equation $I = 0.78 - 0.174 E_0$, where I is the average weekly increase in the erythrocyte count after two weeks of treatment and E_0 is the erythrocyte count before treatment, expressed as millions of erythrocytes per cubic millimeter of blood.

This equation is suggested as a standard for measuring the relative effectiveness of treatment in pernicious anemia.

Observed values equal to or greater than those obtained from this equation indicate adequate treatment. Observed values less than those calculated from the equation indicate inadequate treatment.

The existence of various complicating factors such as concurrent disease, transfusion, or hemorrhage in association with pernicious anemia, invalidate the use of this standard.

HEMOLYTIC ANEMIA, Erythrocyte Morphology in Experimental as Induced by Specific Hemolysin, Tigertt, W. D., Duncan, C. N., and Hight, A. J. Am. J. M. Sc. 200: 173, 1940.

The administration of a specific hemolysin to the donor animal (dog) is followed by a fall in the erythrocyte and hemoglobin levels, proportional to the amount of hemolysin administered and to the titer of the hemolysin.

In the process of cell destruction due to hemolysin (in contrast to the mechanism of hypotonic hemolysis), the erythrocytes approach a spherical form by a diminution in diameter associated with little or no increase in corpuscular volume.

This approach to sphericity is paralleled by proportionately decreased resistance to hypotonic hemolysis.

The length of life in the blood stream of the erythrocytes altered by the hemolysin is inversely proportional to the amount and titer of the hemolysin administered, and survival periods up to one month have been observed.

CEREBROSPINAL FLUID, Calcium and Phosphorus in, in Diabetes Insipidus, Blotner, H. Am. J. M. Sc. 200: 235, 1940.

The concentrations of the calcium, phosphorus, chlorides, and protein were studied in the spinal fluid and blood serum in 10 patients with diabetes insipidus.

The average concentration of the spinal fluid calcium was slightly greater than that of the Ca^{++} content of the serum (1.51 vs. 1.27 mM per liter) in these patients. A series of control patients showed no such difference between their serum Ca^{++} concentrations and cerebrospinal fluid calcium (1.27 vs. 1.24 mM per liter).

Analyses for inorganic phosphate, chloride, and protein showed no significant changes.

Although terse, the book is authoritative, having been written by two outstanding British physicians. It would appear that a text of this nature would also serve admirably for review for advanced medical examinations. The value set on this manual by the profession is attested to by the fact that it has been used successfully for over forty years and has passed through eleven editions. The latest issue is entirely up to date.

In the last section, on clinical diagnosis, the common types of neurologic disease giving rise to vesical abnormalities are discussed and typical examples are given. Many obscure cases of urinary disturbance are dependent on abnormalities of the brain and cord. Disseminated sclerosis ranks next to syphilis in this regard. A certain number of cases are functional. Cystometric methods are emphasized throughout the book. A very good bibliography and index are included.

This book must be read by all who are interested in the urinary bladder, and particularly by urologists and neurologists.

Multiple Human Births*

SEVENTEEN years ago Dr. Newman's book, the *Physiology of Twinning*, was reviewed in these pages. The present volume brings his studies up to date in a popular presentation. It is the first of a series of semipopular books on subjects of science to be published under the sponsorship of the American Association for the Advancement of Science.

Dr. Newman has been most successful in simplifying his presentation for the lay reader and in avoiding technical terminology. Thus, instead of referring to monozygotic twins, he consistently calls them one-egg twins.

With two million twins, triplets, and quadruplets in the United States, there must be ten million persons closely related to twins in one way or another. The volume should, therefore, be of interest to many.

Sections which should be of especial general interest include Siamese Twins, Mirror Imaging, the Dionne Quintuplets, Criminal Twins, and the Life Stories of One-egg Twins who have been reared apart, usually twins who have been left in orphanages. His stories of their chance meetings would be very appropriate for a "Believe It or Not" column.

The Association for the Advancement of Science is to be congratulated for having selected such a thoroughly interesting volume for the inauguration of the series.

The Englishman's Food†

DR. DRUMMOND, who is professor of biochemistry at University College, London, presents almost in novel form an analysis of the foods that the Englishman has eaten since medieval times. The volume represents a tremendous amount of historical research. It possesses a definite medical facet in that the authors analyze the probable food deficiencies in the various centuries, special emphasis being given to the vitamins.

Illustrative of the material covered, Part One deals with Medieval and Tudor England: Production of Food, Quality of Food, Meals of the People, and Their Diet and Health. Deficiency diseases are discussed. The last part, "The Twentieth Century" chapter, deals with dietary problems in the World War. In an Appendix the authors estimate the composition and food value of some of the diets discussed in various parts of the text.

The volume has illustrations gathered from the old English literature.

It may be recommended not only as a reference volume for all who are interested in the history of foods and in nutrition in general but also as a volume of very interesting general reading.

CLINICAL AND EXPERIMENTAL

THE INFLUENCE OF CORONARY SCLEROSIS, CHRONIC CONGESTIVE HEART FAILURE, AND MYOCARDIAL FIBROSIS ON CARDIAC HYPERTROPHY*

MARK E. MAUN, M.D., DETROIT, MICH.

ALTHOUGH the nature of the process resulting in cardiac hypertrophy is incompletely understood, the more accepted theory is that hypertrophy usually follows increased work. This view is most convincingly supported by clinical and necropsy studies. Work hypertrophy, according to this view, is similar to the physiologic growth of muscle. The investigators supporting this theory believe that the hypertrophied heart muscle probably received an adequate blood supply and was relatively free of an inflammatory process during the development of the increased muscle weight.

The inability to explain the observed cardiac hypertrophy in some cases even after careful clinical and post-mortem studies has resulted in the concept that cardiac hypertrophy in many instances may not be due solely to increased work. Numerous hypotheses in addition to increased work have been proposed to explain cardiac hypertrophy. Some investigators believe that in some cases decreased blood supply or myocardial inflammation may result in cardiac hypertrophy. This "injury theory" of Horvath¹ has been supported by both experimental and clinical studies.

It has been suggested^{2, 3} that dilatation is the stimulus resulting in cardiac hypertrophy, whether the cause of the dilatation follows increased work, ischemia, or inflammations. Eyster^{4, 5} has made very significant experimental studies regarding the relationship of dilatation to cardiac hypertrophy. He ob-

*From the Laboratories of St. Joseph's Hospital, St. Paul, Minn., and the Department of Pathology, Wayne University Medical School, Detroit.

Received for publication, April 17, 1940.

served that dilatation always precedes hypertrophy in the experimental animal. He further pointed out that a relatively brief period of dilatation (three to six days) might result in a degree of hypertrophy equal to that seen with experimental aortic valve defects or stenosis. In further studies Eyster produced temporary cardiac dilatation by increasing the blood volume in rabbits that resulted in increased heart weights. Herrmann and Decherd⁶ were unable to confirm the latter experiment in a recent study.

Davis and Blumgart,² in the study of a small number of cases, offer further evidence to support the "injury" concept; they found that those patients presenting congestive failure had hearts weighing more than those without failure. The hearts in their study with severe coronary sclerosis were heavier than those with only a mild degree of coronary sclerosis.

Cardiac hypertrophy has not been noted in experimental cardiac infarction in dogs (Sutton and Davis⁷) nor has it been observed in serial roentgenologic examinations in individuals thought to have a normal-sized heart at the time they experienced a coronary thrombosis (Horine and Weiss⁸). Gross⁹ failed to observe any constant relation between coronary sclerosis and myocardial fibrosis. Miller and Weiss¹⁰ believed that in case of gradual occlusion adequate collateral circulation develops which may forestall hypertrophy. Clawson¹¹ has emphasized that ischemia due to narrowing of the coronary orifices in syphilitic aortitis failed to produce hypertrophy when unassociated with valvular insufficiency. He further points out that any hypertrophy observed in those hearts having coronary sclerosis is more likely to be due to an associated hypertension found in a large percentage of cases than to the coronary sclerosis alone. In a careful study of 420 post-mortem records, Bell and Clawson¹² found coronary sclerosis more frequent in hypertensive than in nonhypertensive individuals and believe there is little evidence to support the concept that hypertrophy is found in an ischemic muscle. Bean¹³ noted hearts with infarcts were usually enlarged when associated with hypertension.

Assuming that ischemia due to coronary sclerosis, congestive failure, or myocardial damage might produce cardiac hypertrophy, it would seem probable that with a severe degree of coronary sclerosis, congestive heart failure, or myocardial fibrosis, the heart would become unusually large; it would be relatively small with only a mild degree of sclerosis or failure. This study was conducted to investigate this point of view.

MATERIAL

The reports of 1,645 autopsies performed at Ancker Hospital were studied. In this group 411 patients were found to have some degree of coronary sclerosis. The post-mortem examinations were done under the direction of Dr. John F. Noble or by myself. It is advantageous to secure the material for a study of this type in which the descriptions of the arteries conform to a uniform pattern, so that the investigator might judge with some accuracy the degree of sclerosis indicated. In order to make an adequate study of post-mortem records one must be familiar with the terminology used by the observer in recording the autopsy. The exact inference of the terms used to describe the coronary

It should be remembered that in the routine post-mortem examinations one does not dissect the entire heart muscle or secure sections from sufficiently numerous areas to be entirely certain that fibrotic patches are not present. In most laboratories the pathologist examines the most superficial portion of the septum and several cut surfaces of the left ventricle. A careful study of the entire heart often reveals surprisingly numerous areas of fibrosis.

Heart Failure.—The presence or absence of heart failure, as well as the degree of failure, was recorded. The more obvious signs of heart failure, such as edema, ascites, and hydrothorax, furnished a great deal of information, but of equal importance was careful gross and microscopic examination of the lungs and liver. Congestion of the lungs was noted to be somewhat proportional to the number of macrophages in the alveoli containing blood pigment. Similarly, the congestion about the central veins of the liver was considered an adequate index of heart failure. A correlation of the microscopic findings in the lungs and liver with the gross observations at the post-mortem examination enables one to classify the case as to the absence or degree of heart failure. Consequently it was graded as absent, mild, or severe.

OTHER CAUSES OF INCREASED HEART WEIGHTS

Coronary sclerosis was noted to be present in hypertrophied hearts whose increased weights were thought to be due to valve defects, adherent pericardium, hypertension, etc. In order to study the effect of coronary sclerosis alone on the heart weight, it was necessary to tabulate the average weight of hearts with coronary sclerosis alone in comparison to the average weight of hearts with coronary disease plus hypertension, adherent pericardium, or valve defects. Should coronary sclerosis alone fail to increase the weight of an observed group of hearts then one would likely consider its effect minimal in other hypertrophied hearts in which coronary sclerosis coexists with hypertension, valve defect, or adherent pericardium.

ISCHEMIA

The effect of ischemia on cardiac weight can be studied by examination of the data in Charts 1, 2, and 3. In order to study the theory that "myocardial injury" due to ischemia might result in dilatation and subsequent hypertrophy, the cases were classified as to their various degrees of coronary sclerosis, ranging from grades I to IV. It was assumed that the hearts with severe sclerosis would have vessels with very small lumina, and hence the muscle would be quite ischemic. The "damage" due to the ischemia or previous infarcts would presumably produce hypertrophy according to the concepts proposed by Horvath.¹ It would then be logical to expect the hearts with severe coronary sclerosis to weigh more than those with minimal vessel changes.

Chart 1 is a record of the entire group studied, representing 305 males and 106 females with varying degrees of coronary sclerosis arbitrarily divided in grades I to IV sclerosis, depending on the degree of narrowing of the vessels. In these 411 patients coronary sclerosis is associated with all other possible causes of hypertrophy. In the 52 most ischemic male hearts (grade IV) the average weight is seen to be 365 Gm. while the hearts with grade III sclerosis

weigh 408 Gm. Grade III cases, which should have less blood supply than those with grade II sclerosis, have an average weight of 429 Gm. A total of 119 male hearts with grade I sclerosis weigh 415 Gm. These hearts are heavier than the apparently more ischemic group with grade III sclerosis. Examination of the female patients tabulated in Chart 1 reveals those with grade IV coronary sclerosis have an average weight (367 Gm.) greater than those with grade I sclerosis (339 Gm.), but less than those with grade II and III sclerosis (386 and 382 Gm., respectively).

Chart 1.—Coronary sclerosis. All cases.

Chart 2.—Heart weight with coronary sclerosis and hypertension. See Chart 1 for key.

In Chart 1 coronary sclerosis is present with hypertension, adherent pericardium, valve defects, etc. It is apparent, however, that the weight of the heart is not related to the degree of observed coronary sclerosis and probable ischemia present. From these data the evidence points to the fact that the heart weight is dependent on factors other than coronary disease. The average weights of the hearts in various grades of sclerosis would seem to be a matter of chance selection.

Several investigators have noted that hearts with severe coronary sclerosis and cardiac hypertrophy usually have an associated hypertension. It is also striking that a group of hearts with coexisting hypertension and coronary disease (Chart 2) have an average weight greater than that of an unselected group of hearts (Chart 1), and that this weight is far in excess of that of a group of hearts with coronary sclerosis alone (Chart 3). The latter group in this study fail to show any evidence of an average increased weight due to coronary sclerosis alone. A comparison of these charts indicates that a heart with hypertension will likely be hypertrophied with or without coronary sclerosis, while those hearts with coronary sclerosis alone will likely be approximately normal in weight. In order to re-emphasize the causal relationship of coronary disease to hypertension 157

hearts are tabulated in Chart 2. In this group there is some clinical or anatomic evidence of hypertension in addition to the sclerotic changes of the coronary vessels as observed in the post-mortem specimens. This study verifies Clawson's¹¹ opinion that there is a very close relationship between hypertension and coronary sclerosis.

HYPERTENSION AND CORONARY SCLEROSIS

Chart 2 is a study of those cases in which the heart weights might be due to either hypertension or coronary sclerosis, or both. From a study of this group the hearts (male) with grade IV sclerosis have an average weight of 523 Gm., which is somewhat more than those with grades III and II sclerosis (469 and 486 Gm., respectively). The average weight of the 29 hearts with grade I coronary sclerosis and hypertension is 514 Gm., which is much greater than the more ischemic hearts with grades II and III sclerosis.

There are 46 females tabulated in this group. In this series, those hearts with grade II sclerosis weigh 451 Gm., while those with grade IV sclerosis weigh 441 Gm. Hearts with grade III have an average weight of 432 Gm. as compared to an average of 438 Gm. with grade I coronary disease. This would also indicate that the heart weight is unrelated to the muscle ischemia or "injury." It would be assumed that the heart weights are influenced in this group by the presence of hypertension, since all grades of coronary sclerosis show a variable degree of hypertrophy. Ischemia apparently has little influence on the weights of hearts in the presence of an existing hypertension.

Coronary Sclerosis Alone.—A survey of the 159 male hearts reveals the average weight to be less than 372 Gm., which would not be considered a hypertrophied heart in comparison to average adult male hearts in the material examined in this department. It is also striking that the average weight of the hearts in this group is 50 to 75 Gm. less than those in Chart 2 that have an associated hypertension. The average weight of the hearts studied in Chart 3 is also considerably less than those in Chart 1 in which the heart weight might be due to coronary sclerosis plus hypertension, adherent pericardium, or valve defects. A comparison of these charts confirms Clawson's opinion that hypertension is the likely cause of the increased heart weight in those cases with both hypertension and coronary sclerosis.

A total of 208 hearts are tabulated in Chart 3 in which coronary sclerosis is the only possible cause of the increased heart weight. Additional factors that might produce hypertrophy were excluded after careful examination of clinical records and post-mortem studies. In this group the effect of ischemia on cardiac weight can be correctly analyzed, since no other factor that might produce hypertrophy is present.

One would expect hearts with the more ischemic muscle to be the largest if coronary sclerosis produced hypertrophy. The average weight of 23 male hearts with grade IV sclerosis is 357 Gm., while the weight of the less ischemic hearts (grade III sclerosis) is 371 Gm. The 70 hearts with grade I sclerosis have an average weight of 349 Gm., while those with grade II sclerosis have an average weight of 334 Gm.

The average weight of the female hearts tabulated in Chart 3 is not proportional to the degree of coronary sclerosis present, nor are the hearts larger than the normal hearts encountered in this department. The heaviest hearts are found to have an average weight of only 371 Gm. (grade III sclerosis). These data fail to confirm the theory that ischemia, or "cardiac injury," produces hypertrophy, since the hearts with mild coronary disease are approximately the weight of those with severe coronary sclerosis.

Davis and Blumgart have presented evidence to show that chronic congestive heart failure may in itself produce hypertrophy. The view is divergent to the common concept that congestive failure is seen in a previously hypertrophied heart.

Chart 3.—Heart weights in cases of coronary sclerosis without hypertension. See Chart 1 for key.

Chart 4.

Chart 4.—The relation of chronic congestive heart failure to heart weight

CHRONIC CONGESTIVE FAILURE

Chart 4 is a record of 222 patients showing some degree of coronary sclerosis associated with some degree of chronic congestive heart failure in some cases and no failure in others. Since in the preceding charts coronary sclerosis was found to have little influence on the heart weight, congestive failure would be the only factor influencing the weight in these cases. Hypertension and the other usual causes of cardiac hypertrophy are not present in the cases studied in Chart 4. Should one assume that chronic congestive failure produces cardiac hypertrophy, then the hearts with severe failure should have an average weight greater than the weight of those with mild failure, while both should weigh more than the group with no gross or microscopic evidence of heart failure.

Examination of the data shows the average weight of all the hearts to be from 50 to 75 Gm. less than those usually considered in the hypertension group in this department. The weights of the entire group approximate the weights of the hearts due to coronary sclerosis alone (Chart 3). The patients with severe heart failure weigh approximately the same as those with mild heart failure and those with no evidence of heart failure. There is little convincing evidence from this study that chronic congestive failure might produce cardiac hypertrophy.

MYOCARDIAL FIBROSIS

From an anatomic viewpoint one might observe the influence of "myocardial injury" by noting the effect of myocardial fibrosis on the heart weights. Fifty-seven patients have been classified in Chart 5 as to their degree of myocardial fibrosis and heart weights—all other possible causes of increased heart weight have been excluded after a careful study of the clinical records and examination of both the gross and microscopic specimens. It is surprising that male hearts with grade IV fibrosis weigh less than those with grade I. The hearts with grade III fibrosis also weigh less than those with grade II fibrosis. Consideration of the data in regard to the male specimens would indicate that in the presence of myocardial damage the average weight is about equal to that of a normal heart. In the same chart the average weight of the female specimens increased as the myocardial fibrosis became more severe. The material presented adds no support to the theory that myocardial injury will produce cardiac hypertrophy.

Chart 5.—Relation of myocardial fibrosis to hypertrophy.

In this study only 25 persons were found to have thrombosed coronary arteries. Since the majority of these were found to have gross or microscopic evidence of hypertension, the number is too small to reach any conclusion in regard to the relation of thrombi and cardiac hypertrophy.

The data in this material were examined by statistical methods. A comparison of the average weights was shown to be sufficiently accurate in a study of this kind.

DISCUSSION

A total of 411 cases of coronary sclerosis were studied. An attempt was made to correlate the heart weight with the degree of coronary sclerosis, "myocardial damage," and congestive failure present. Practically all investigators found it difficult to explain satisfactorily the observed increased heart weight in a small percentage of the specimens seen at post mortem. For a few of this group, several investigators have suggested that an injured myocardium may be

the stimulus that results in subsequent hypertrophy. An obvious cause of such injury would likely be decreased blood supply due to coronary sclerosis. This theory has received support by competent observers who have frequently noted severe coronary sclerosis as the only obvious explanation of the increased heart weight. In addition to the presence of disturbed nutrition, Davis and Blumgart² have presented some evidence to show that chronic congestive failure may be associated with hypertrophied hearts.

In contrast to these views other workers have failed to observe any evidence of increased heart weight due to coronary disease that might produce ischemia or myocardial injury. The usual belief is that adequate blood supply is necessary for any muscle hypertrophy. These investigators also found a close correlation between cardiac hypertrophy and hypertension.

To study the effect of ischemia on hypertrophy the hearts were separated into various grades of coronary sclerosis, and the average heart weight was determined in the various groups. No correlation was noted between the degree of sclerosis present and the heart weight at post mortem. It was found that hypertension was the usual cause of the increased weight and that those patients with coronary sclerosis alone as the explanation of the heart weight could not be placed in the hypertrophied group.

Eyster^{4, 5} presented experimental hypertrophy in dogs by producing dilatation of the ventricle by means of an experimental valve defect or aortic stenosis. Hypertrophy followed the stretching of the muscle fibers. The hypertrophy was considered a reaction to the "myocardial damage." Similarly, others have reasoned that the increased diastolic volume in a failing heart may result in stretching the muscle fibers and thereby result in hypertrophy.

The effect of chronic congestive failure on heart weight was studied by comparing the average weight of the cases with no heart failure, mild failure, and severe failure. After eliminating all other factors, those patients without heart failure were found to be equal in weight to those with severe failure. There was little evidence that the presence of heart failure would influence the heart weight.

In order to approach the injury thesis from another viewpoint the weights of the hearts with various degrees of myocardial fibrosis were compared. It was assumed that the amount of fibrosis present was some index of the myocardial injury. If the injury thesis is correct, it is reasonable to assume that the hearts with severe fibrosis would be larger than those with mild degree of fibrosis. From this study there is no correlation between the degree of fibrosis and the observed heart weight.

CONCLUSIONS

1. The average weight of 411 hearts and the degree of coronary sclerosis were compared.
2. There was no correlation between the degree of coronary sclerosis and the heart weight.
3. Hypertension was the usual explanation of the increased heart weight, and a close relationship between coronary sclerosis and hypertension was noted.

4. The hearts with no heart failure were found to weigh approximately the same as those with chronic congestive heart failure.

5. No evidence was found to support the concept that myocardial fibrosis may produce cardiac hypertrophy.

DISSECTING ANEURYSM OF THE AORTA*

A SUMMARY OF CLINICAL SYNDROME AND PATHOLOGY TOGETHER WITH REPORT OF A CASE SHOWING UNUSUAL PATHOLOGIC FEATURES

FREDERICK W. NIEHAUS, M.D., AND WILLIS D. WRIGHT, M.D., OMAHA, NEB.

DURING the last decade many cases of dissecting aneurysm have been reported. Several comprehensive reviews^{1, 4, 17} have appeared in the literature describing the pathology^{10, 16, 17} and the clinical features.^{2, 3, 7} With this interest in the subject the number of cases diagnosed ante mortem, and corroborated by autopsy, has greatly increased.

These cases have been so well described and carefully studied pathologically and clinically that it seems superfluous to record another case, unless new features have been observed. Our case herein described presents some unusual features. Deep longitudinal grooves of the ascending and the transverse arch of the aorta, causing narrowing of the isthmus, are mentioned only in one other case, which was reported by Klotz and Simpson.⁶ Our case contributes clinically to the evaluation of the electrocardiogram in dissecting aneurysm.

*From Medical Department, University of Nebraska College of Medicine, Omaha.
Received for publication, April 18, 1940.

REPORT OF CASE

History.—W. Mc., a negro porter, aged 49 years, was seized by a sudden severe pain on November 2, 1937, at 7 P.M., while standing on a depot platform waiting for passengers to board a train. At this stop no passengers left or entered the train, so that he had no baggage to carry. The only exertion immediately prior to the onset of the pain consisted of carrying a small stool such as is usually placed at the foot of passenger car steps.

Pain.—The onset was very sudden and extremely severe. He was prostrated and "broke out in a cold sweat." He was put to bed in a berth.

At the onset the pain radiated to his neck and jaws, then seemed to penetrate to his back in the lower thoracic region, then radiated downward to the lumbar region and the backs of his thighs as far as his knees. In about an hour the pain localized in his upper abdomen. At 11 P.M. he was met at the train by one of us (W. D. W.) and immediately sent to a hospital. The pain at this time was localized in the epigastrium and the lower sternal region, radiating to the interscapular region and along both costal margins, being more marked toward the right side. The pain persisted at this site until death occurred, twenty-one hours after the onset. The severity remained intense in spite of the liberal use of morphine.

Fig 1.—Electrocardiogram showing inverted T_1 and T_2 and depressed S-T segment and absent Q in Lead IV.

On arrival at the hospital the pulse rate was sixty per minute, the blood pressure was 140 systolic and 100 diastolic. He had not vomited, but was moderately distended. The epigastric pain was intense. There was marked tenderness with some muscle spasticity of the epigastrium and the right upper abdominal quadrant, stimulating upper abdominal disease. The next morning at 8 A.M. the pain remained localized in the epigastrium, still very severe, except when ameliorated by opiates.

Examination.—Examination showed a robust, obese negro, weighing about 200 pounds, appearing to be critically ill and in agony. His face was suffused and veins of his neck were moderately distended. There was only a slight respiratory difficulty. The pupils reacted to light and were equal in size. The lungs showed no change of density or râles anteriorly or laterally. On account of his critical condition it was not deemed advisable to turn him.

The heart showed the apex in the anterior axillary line in the fifth interspace. There was an extension of dullness to the left in the third interspace. The rhythm was regular. The pulse rate was 100 per minute. There was a definite protodiastolic gallop rhythm, and a diastolic murmur at the aortic area and along left sternal border. The epigastrium and the right upper abdominal quadrant were tender and moderately spastic. The blood pressure was systolic 140 and diastolic 100.

Urinalysis: The urine was acid and had a specific gravity of 1.037. It showed albumin 2+, and was negative to sugar. Microscopic examination revealed numerous pus cells.

Blood: The hemoglobin was 15.6 Gm., erythrocytes were 4,700,000 and leucocytes 9,000. The differential count showed segmented cells 51 per cent, staff cells 14 per cent, lymphocytes 30 per cent, and monocytes 5 per cent. The icteric index was 6. The sedimentation rate was 3 mm. in one hour. The blood Wassermann reaction was negative.

An electrocardiogram (Fig. 1) taken at 8:30 A.M. on November 3, 1937, showed evidence of coronary thrombosis. The clinical picture, while atypical, indicated a circulatory disorder. Together these seemed to justify the diagnosis of coronary occlusion. The patient's condition remained unchanged until 4 P.M. (twenty-one hours after onset) when he suddenly died while taking a drink of water.

The following findings were available from the company's records of periodic examinations made by Dr. L. Chaffin of Los Angeles.

Feb. 20, 1923: Weight 175½ pounds. Blood pressure 122/85, Wassermann 4+. Urine showed a trace of albumin.

Feb. 15, 1924: Weight 201½ pounds. Blood pressure 130/80.

March 15, 1925: Weight 206½ pounds. Blood pressure 135/78. Faint trace of albumin was present in urine.

Jan. 12, 1932: Weight 220 pounds. Blood pressure 230/140. Urine negative.

Jan. 15, 1933: Weight 215 pounds. Blood pressure 226/124. Urine negative. Left side of heart enlarged.

Jan. 9, 1934: Weight 215 pounds. Blood pressure 210/124. Urine negative. Teeth carious. Left side of heart enlarged. No murmurs. Varicose ulcer on left leg.

Aug. 22, 1933 to Feb. 2, 1934: Disabled on account of varicose ulcer on left leg.

Jan. 28, 1935: Weight 215 pounds. Blood pressure 200/120. Varicose ulcer healed. Urine negative.

Jan. 13, 1936: Weight 210 pounds. Blood pressure 200/130. Urine; specific gravity 1.020, albumin 2+, sugar negative. Varicose veins on left leg.

Autopsy.—The autopsy performed by Dr. A. S. Rubnitz showed the following significant findings: The pericardial sac was widely distended, containing about 1,000 c.c. of clotted blood. After removing this, a large subpericardial hematoma enveloped the origin of the aorta, the pulmonary artery, and the right auricle. The aorta showed irregular triangular rupture (Fig. 2) 1.5 cm. in length, about 2.5 cm. above the aortic valve ring. This was located on the right lateral surface, slightly anteriorly, and extended through the intima and about four-fifths of the media. From the site of this rupture the blood had burrowed toward the heart, involving almost all the circumference of the aorta, and thence extended subpericardially over the surface of right auricle as described. The site of rupture through the visceral pericardium could not be demonstrated. The intramural hematoma extended distally from the site of the rupture along the ascending, the transverse, and the descending arch of the aorta, terminating at the level of the fourth thoracic vertebra. The extent of the circumference dissected varied from about one-half at the site of the rupture to one-fourth at its termination. The aorta showed minimal arteriosclerotic changes. The ascending arch shows small slightly elevated yellowish plaques, the largest being not over 3 mm. thick. There was no gross evidence of mesaortitis. At the site of rupture the aortic wall showed no further defects. The torn edge showed a normal thickness of media and a minimal intimal thickening. At the juncture of the ascending and the transverse arch of the aorta there were four or five peculiar longitudinal grooves (Fig. 3), measuring 1.5 cm. in diameter; these reduced the size of the lumen of the aorta considerably. Beyond this the arch widened to what appeared to be a normal diameter. The size of the intimal arteriosclerotic plaques increased in size (0.5 cm.), and were more numerous in the lower thoracic and the abdominal aorta. However, throughout the entire length of the aorta there were no atheromatous ulcers or calcified plaques.

The left ventricle of the heart was moderately hypertrophied. The right side of the heart was dilated. There was no thickening, retraction, or sclerosis of any of the heart valves. In view of the fact that syphilis has been considered as an etiologic factor in rupture of the aorta, it is particularly noteworthy that in this case the aortic ring was not widened, the aortic cusps were soft, thin, and free from fibrotic changes or retractions.

Fig. 2.—Photograph showing site of aortic rupture and folds in aorta.

The coronary arteries presented no narrowing of orifices. The branches were opened to their terminations. There was no thrombus or narrowing of the lumen. In a few places there was slight intimal thickening appearing as subintimal yellow plaques, but no atheromatous ulcers or areas of calcification were present. There was a moderate tortuosity of the larger branches of the coronary arteries on the surface of the myocardium. Lungs showed marked congestion. Kidneys showed few small cysts. The other organs showed no significant changes.

Dr. H. E. Eggers, Professor of Pathology at University of Nebraska, reported the following microscopic examination of the aortic wall: Sections were cut both through the involved portion and what appeared to be an intact portion of the vessel. The latter section showed no evident change, whereas the former revealed a zone of necrosis of the media, extending for some distance as a narrow band, but widening centrally, and disrupted in the widest part. To the extent that the vasa vasorum could be distinguished, these were intact, even in close proximity to the diseased area. None could be found in the necrotic portions proper. Hemorrhage was noted in the gap where disruption of the wall occurred.

PATHOLOGY OF DISSECTING ANEURYSMS OF AORTA

Recent authors⁹ generally do not consider syphilis as an etiologic factor. Klotz and Simpson⁶ logically state that a granulomatous inflammatory process like syphilis would tend to weld the lamellae more closely together, so that "the wall would split less easily into its anatomic layers." Our patient showed a negative Wassermann at the time of this attack, the aortic wall showed no gross or microscopic evidence of syphilis, and the aortic cusps were entirely normal. In spite of the fact that this patient had a record of a four-plus Wassermann reaction of the blood in 1923, there was no evidence of a syphilitic process in the aorta at the time of autopsy.

Fig. 3.—Drawing showing: I, Rupture of aortic wall; II, longitudinal grooves which narrowed the lumen of the aorta; III, orifice of right coronary artery; and IV, orifice of left coronary artery.

Changes in the media mentioned by Gsell,¹⁸ described by Erdheim¹⁶ as an idiopathic cystic medial necrosis, and elaborated by Moritz,¹⁷ are accepted as the characteristic lesion. This is described as "small areas of necrosis and peculiar hyalinized vacuoles in the media," showing "no inflammatory or reparative process." These form "peculiar cystic spaces between elastic fibers." The vasa vasorum may rupture into these spaces, forming a hematoma which splits the layers of the media. These may rupture the intima secondarily;¹⁰ probably primary rupture through the intima occurs more frequently. Tears nearly always occur in the ascending arch of the aorta. Dissection usually occurs between middle and outer thirds of the wall, and involves one-third to one-half of the circumference of the aorta. This dissection may extend toward the heart, entering the pericardial sac and surrounding part of the heart with a hematoma; it may interfere with the coronary circulation, and finally terminate by rupture into the pericardial sac.³ Our case is an example of this course,

which explains some of the symptoms and the electrocardiographic findings. Others³ have described rupture into the mediastinum, pleural cavity, or abdomen. This channel may re-enter the aorta forming a "double barreled" aorta.

The dissection produces decided effects on the vessels originating directly from the aorta³ and may result in (a) severance as in the case of the intercostal arteries, (b) partial or rarely complete obstruction by the hematoma, (c) extension of the dissection along the larger branches such as the renal vessels, or (d) disruption of the periarterial sympathetic plexus resulting in a spontaneous periarterial sympathectomy.⁹ These would produce bizarre vascular and neurologic symptoms and signs, such as changes in the pulse, paresthesia, hyperesthesia, anesthesia, or paralysis. Death occurs by rupture of the sac of the hematoma into a cavity, and very rarely by cardiac failure.

TABLE I

FEATURES	DISSECTING ANEURYSM OF AORTA	CORONARY THROMBOSIS
Onset	(1) Sudden (2) With exertion	(1) Sudden (2) Usually at rest
Pain		
(a) Character	Extremely severe, tearing	Severe
(b) Radiation	Widespread, chest, abdomen back thighs; arms rarely	Chest, neck, arms usually
(c) Duration	Minutes to days	Hours to days
Syncope	Frequent	Rare
Shock	Frequent with normal, or elevated blood pressure	Frequent with low blood pressure
Fever	Moderate	Low
Leucocytosis	Moderate	Low
Pulse	Often unequal, may be decreased or increased	Usually equal
Hypertension	Usually present or history of such; may vary in two arms	With attack usually low, may or may not be history of such; same both arms
Pericarditis	None	Pericardial friction rub present at times
Diastolic murmur	Important sign	Not related to condition
Hematuria	May be present	None
X ray	Deformity of aorta, rapidly increasing in size	Probable changes of heart size and shape
Electrocardiogram	If negative, important finding ¹⁴	Usually presents typical electrocardiogram
Neurologic	Bizarre, paresthesia, anesthesia, hyperesthesia, paralysis from circulatory interference	Usually absent; when present due to emboli
Venous pressure	Extremely high if cardiac tamponage	High with congestive failure

In our case the peculiar longitudinal grooves (Fig. 3) involving the distal part of the ascending and the proximal part of the transverse arch of the aorta were conspicuously present. This reduced the size (1.5 cm.) of the lumen considerably, and thereby may have caused an increase of pressure with systole in the first part of the ascending aorta. These grooves have hitherto been mentioned in only one other case, which was reported by Klotz and Simpson.⁶ The aortic wall was not thickened between these grooves. They give the impression of being formed by a decrease of substance in the aortic wall, as if the grooves were the marks on the intimal surface of subjacent longitudinal vacuoles. Microscopic examination of the wall of the aorta by Eggers showed the typical medial changes described by Erdheim.¹⁶

CLINICAL MANIFESTATIONS

The symptoms and signs of a dissecting aneurysm have been clarified by extensive and thorough study of the pathology, so that a clinical syndrome can be synthesized.

1. The onset is usually sudden and violent.³
2. The pain is extremely severe and agonizing,³ described as having a tearing quality, accompanied by a sense of annihilation. A few persons are reported who suffered no pain during the illness.^{7, 11}
3. The duration of the pain is from minutes to days.
4. The radiation of the pain is widespread and bizarre. It usually begins in the anterior part of the thorax, spreading to the neck, to the back in the thoracic, the lumbar, or the sacral regions, to the thighs or to the upper part of the abdomen. Radiation of pain to the arms rarely occurs, but when present, it is felt on the outer surface of the arms.⁷
5. Syncope¹ and shock occur in nearly all cases. Shock in this condition, is frequently not accompanied by the usual drop in the blood pressure. Nausea and vomiting are common.
6. Fever and leucocytosis of a moderately high degree are present in most cases.
7. Circulatory phenomena.⁷
 - (a) The peripheral pulses may be altered. The dissection of the layers of the aorta and resultant hematoma may partially obstruct the branches leaving the aorta, resulting in a diminution of pulse tension and volume in this vessel. The degree varies from a slight decrease to almost complete obliteration. In the case of an extremity this results in varying degrees of numbness, coldness, and weakness. The pulsation may, however, be increased, if the dissection extends onto the branching vessel, thereby producing a spontaneous periarterial sympathectomy.⁷ This mechanism may have an influence in maintaining a normal pressure in the presence of systemic signs of shock. In the case of the renal vessels and kidneys, this circulatory disturbance may cause hematuria.¹¹
 - (b) Hypertension is usually present, although a number of cases have been recorded with the presence and the history of a normal blood pressure.^{9, 10} There may be an inequality of pressure in the arms.
 - (c) A diastolic aortic murmur⁷⁻⁹ has frequently been reported. Hamburger and Ferris record the development of such a murmur during their observation of a case of dissecting aneurysm. This murmur was distinctly evident in our patient. Such a finding is not accompanied by the peripheral signs of aortic regurgitation.
 - (d) A hematoma in the mediastinum or blood in the pericardium may produce signs of cardiac tamponade, with widely distended cervical veins and a very high venous pressure, as was present in our case. At autopsy this was accounted for by the presence of a large amount of blood in the pericardial sac.
 - (e) Roentgenologic signs²⁰ consist of a deformity of the supracardiac shadow, or of the aorta, which may rapidly increase in size. If the shadow pulsates, it is a particularly reliable sign.

- (f) The electrocardiogram¹ is frequently not modified, but cardiac dissection of the aneurysm may disturb the coronary circulation sufficiently to produce an electrocardiogram, indicating a coronary obstruction.¹³ This was exemplified in our case (Fig. 19).

NEUROLOGIC SIGNS

Hemiplegia may be caused by dissection extending cephalad along the left carotid artery, thereby obstructing this vessel.

Bizarre neurologic symptoms, such as paresthesia, anesthesia, hyperesthesia, or even paralysis, may result from circulatory interference to the extremities or other parts. As previously mentioned, the intercostal vessels may be torn from the aorta. Even larger vessels may be torn from their site of origin or the dissection extending along their walls with hematoma formation may more or less obstruct their lumina. Increased heat of an extremity may be produced by spontaneous periarterial sympathectomy as already mentioned.

DIFFERENTIAL DIAGNOSIS

The onset and course of a dissecting aneurysm of the aorta and coronary thrombosis present many common features. An attempt at differentiation is shown in Table I.

SUMMARY

1. A case of dissecting aneurysm of the aorta, showing peculiar longitudinal grooves of the isthmus, is presented.
2. A synthesis of a clinical syndrome is attempted from the pathology, symptoms, and signs.

SULFAPYRIDINE OVERDOSAGE—ANTIDOTAL ACTION OF HYPNOTICS IN ANIMALS*

WITH A NOTE ON SULFATHIAZOLE

RICHARD KOHN RICHARDS, M.D., NORTH CHICAGO, ILL.

SULFAPYRIDINE

THE first reports on the toxicity of sulfapyridine in experimental animals by Wien¹ seem to indicate a lower toxicity of this drug as compared with sulfanilamide. However, subsequent studies, particularly by Marshall, Bratton, and Litchfield,² have shown that the incomplete absorption due to the low solubility of sulfapyridine is responsible for the alleged lower toxicity. If this factor is taken into consideration, sulfapyridine is actually somewhat more toxic than sulfanilamide. Marshall and Long³ have described the acute toxic effects following the intravenous injection of sodium sulfapyridine in rabbits and dogs. Their results have been entirely confirmed in experiments conducted in our laboratory.

The well-known serious complications which may follow sulfapyridine treatment, as hemolytic anemia, agranulocytosis, jaundice, etc., call for particular care in the use of this drug, but fortunately are rare. Vertigo, nausea, and vomiting are less dangerous, but are still very annoying side actions of the sulfapyridine treatment and occur much more frequently. In the following, an attempt was made to approach experimentally the possibility of alleviating these symptoms.

Experiments in Rabbits.—In order to secure clear-cut results with respect to toxic effects and their possible management, we have used in all experiments the intravenous injection of a 20 per cent sodium sulfapyridine solution. Such a solution has a pH of 10 or 11 and a high titrable alkalinity. One and one-half to two minutes were always consumed in administering the total dose. Male and female rabbits, weighing approximately 3 to 5 pounds, were used. While 500 mg. per kilogram regularly produced convulsions, 800 mg. per kilogram were fatal in 70 per cent of the animals. A total of 1,000 mg. per kilogram always caused death from secondary depression or pulmonary edema after convulsions. A total of 1,200 mg. per kilogram killed the animals within a few minutes following violent tonic or clonic convulsions. Thus, the picture of the acute poisoning presented itself as an initial marked stimulation, quickly followed by depression of the central nervous system. The convulsions were of the spontaneous type, and could not be provoked as a reflex to stimulation; in this respect they resembled picrotoxin convulsions. This observation suggested that they might be combated by means of hypnotics.

*From the Abbott Laboratories, North Chicago.

Received for publication, April 19, 1940.

Urethane was used in the first experiments. The minimum hypnotic dose for rabbits is 500 mg. per kilogram of this drug intravenously. The M.L.D. lies between 1,700 and 1,800 mg. per kilogram. The urethane was injected intravenously as a 25 per cent solution mixed with 1,000 mg. per kilogram of sulfapyridine. This amount of sulfapyridine alone would kill 100 per cent of the animals. The results obtained with varying amounts of urethane combined with this dose of sulfapyridine can be seen in Fig. 1 in the form of a dose mortality curve representing data on 35 animals. The mortality is zero with the use of 150 mg. per kilogram of urethane, an amount which, by itself, has no noticeable influence on a normal rabbit. In combination with sulfapyridine

Fig. 1—Intravenous injection of sulfapyridine (1,000 mg. per kilogram) and urethane in rabbits.

there was slight twitching or occasional convulsions, but all six animals on this dose survived. This represents the optimal antidotal effect, since the mortality increases with either a larger or smaller urethane dose. With smaller doses, the protective action against the convulsions is insufficient; with larger doses, the convulsions disappear but a general depression quickly develops which leads eventually to respiratory paralysis. This death from depression occurs with doses of urethane which are innocuous to the normal animal, and seem to represent a summation of the depressant urethane effect and the second, depressant phase of sulfapyridine action.

Attempts to antidote 1,200 mg. per kilogram of sulfapyridine with a single urethane injection were unsuccessful. Repeated urethane injections, when made during the convulsive state of the sulfapyridine poisoning, occasionally saved the life of the animals.

It is well known that barbiturates are particularly effective in suppressing convulsions. The antidotal effect of sodium pentobarbital (nembutal) on sulfapyridine convulsions was, therefore, studied in a similar way. In rabbits 15 mg. per kilogram intravenously is the minimum hypnotic dose for nembutal and 45 mg. per kilogram the L.D. 50. Mixtures of different amounts of this drug with either 1,000 or 1,200 mg. per kilogram of sulfapyridine were injected intravenously. The results on 48 animals are given in Fig. 2. In general, the effect is similar to that of urethane, but a definite antidotal action is present even against the extremely high dose of 1,200 mg. per kilogram of sulfa-

Fig. 2.—Intravenous injection of sulfapyridine and pentobarbital sodium in rabbits.

— 1,200 mg. per kilogram of sulfapyridine.
 - - - 1,000 mg. per kilogram of sulfapyridine.

pyridine. These curves also show an optimum antidotal effect at the normal hypnotic dose level of 10 mg. per kilogram. Smaller doses are unable to prevent convulsions, and larger ones, which are tolerated by normal animals, lead to respiratory paralysis. Finally, we conducted experiments using only 700 mg. per kilogram of sulfapyridine in order to see how high the dose of nembutal could be raised without producing cumulative depression. The maximum dose of nembutal which could be tolerated under these circumstances was 40 mg. per kilogram; therefore, with moderately high doses of sulfapyridine the toxicity of nembutal is not significantly enhanced.

The effect of large doses (1 to 3 Gm. per kilogram) of sodium bromide given orally on the convulsive action of 1,000 or 1,200 mg. per kilogram of sulfapyridine injected one-half hour later was also studied. Death could be pre-

vented only rarely, though the fatal outcome was somewhat delayed. Intravenous injection of magnesium sulfate (25 to 150 mg. per kilogram) or premedication with 35 mg. per kilogram of morphine subcutaneously were ineffective.

Experiments on Dogs.—While rabbits lend themselves only to the study of the more violent reactions, dogs show symptoms of sulfapyridine intoxication more like those seen in man. After the injection of 400 mg. per kilogram, unsteadiness of gait, signs of subjective discomfort, and repeated vomiting, frequently accompanied by urination and defecation were the rule. Twitching and, occasionally, convulsions developed. Convulsions were always present with 500 mg. per kilogram. Of 9 animals 2 died following this dose. Attempts to prevent the vomiting by the injection of 3 to 5 mg. of atropine sulfate fifteen minutes before the sulfapyridine proved to be entirely ineffective. Nembutal was added to the sodium sulfapyridine in varying amounts. The results are summarized in Table I. Ordinarily 15 mg. per kilogram is the minimum hypnotic dose, while 50 mg. per kilogram is the M.L.D. 50 of this barbiturate.

TABLE I

SODIUM SULFAPYRIDINE AND SODIUM PENTOBARBITAL (NEMBUTAL) INTRAVENOUSLY IN DOGS

CURRENT NO.	SODIUM SULFAPYRIDINE MG./KG.	SODIUM PENTOBARBITAL (NEMBUTAL) MG./KG.	NO. OF DOGS	NO. SURVIVED	REMARKS
1	400	-	2	2	Unsteadiness of gait, vomiting, defecating, convulsions
2	400	5	2	2	Atactic, vomiting, no convulsions
3	400	10	3	3	Slightly atactic, then relaxed. Two slept
4	400	15	1	1	Atactic, first restless, later quiet
5	400	30	2	2	Sleep
6	400	35	2	2	Sleep
7	400	40	4	2	One died of pulmonary edema, one of respiratory paralysis
8	400	50	3	2	One died of respiratory paralysis
9	500	-	9	7	Symptoms as under (1) but more severe
10	500	10	1	1	Atactic, vomiting
11	500	20	1	1	Light sleep

In Table I, 5 mg. per kilogram prevent convulsions but not vomiting, while 10 to 15 mg. per kilogram suppress not only the convulsions but also vomiting and the other signs of subjective discomfort. The dogs quieted down or even went into a light sleep. The sensitivity to nembutal appears to be slightly increased, since a dose of 40 mg. per kilogram of nembutal which is usually well tolerated may cause deaths in conjunction with sulfapyridine. The increase of the sulfapyridine dose to 500 mg. per kilogram necessitates a somewhat larger dose of nembutal to prevent toxic symptoms. Dogs in which convulsions had developed after the administration of sulfapyridine could be caused to sleep by the injection of a small amount of the barbiturate. These animals recovered promptly.

DISCUSSION OF RESULTS

The mortality curves of sulfapyridine in combination with either urethane or nembutal in rabbits seem to support the assumption that sulfapyridine has a

biphasic action upon the central nervous system. If a hypnotic is given in a dose high enough to prevent convulsions, the animal can survive this first stage of the sulfapyridine effect. It seems, however, that the convulsive and the depressant actions overlap to some extent, since a relatively small increase in the dose of the hypnotic rapidly brings about a summation of the depressant component. It is of particular interest to note that with nembutal, and especially urethane, subhypnotic doses are the safest and most effective.

If it is true that secondary death in depression is due to a combined action of the barbiturate and sulfapyridine, it should be possible to prevent these by the use of an analeptic. We have tried to prove the correctness of this assumption experimentally. It is known that the intravenous injection of picrotoxin is followed by its typical stimulating effect only after a latent period of a few minutes. Making use of this property, we have injected rabbits intravenously with 1,200 mg. per kilogram of sulfapyridine and added doses of nembutal sufficiently large to cause deaths when so combined with sulfapyridine. Picrotoxin in doses of 1 to 1.5 mg. was added to this mixture. None of four animals receiving a mixture of 1,200 mg. per kilogram of sulfapyridine, 30 mg. per kilogram of nembutal and 1.5 mg. per kilogram of picrotoxin died. But, as can be seen from Fig. 2, all animals died if no picrotoxin is added to such a mixture. Similarly, 2 of 3 animals survived when the sulfapyridine was mixed with 25 mg. per kilogram of nembutal and 1 mg. per kilogram of picrotoxin. None of these animals showed convulsions and all recovered promptly from what appeared to be a pure nembutal sleep. This experiment seems to give further support to the theory of a biphasic action of sulfapyridine.

Adriani⁴ has recently published experiments in which he tested the toxicity of the different anesthetics on rats which were pretreated with very high doses of sulfanilamide for three days. He found that while volatile and gaseous anesthetics, as well as avertin, were tolerated as well as they are by normal animals, the barbituates became anesthetic in subanesthetic doses and lethal in anesthetic doses. We repeated these experiments in rabbits and obtained similar results, provided very high doses of sulfanilamide were used (1,500 mg. per kilogram daily for three days). However, with moderately large doses of sulfapyridine (700 mg. per kilogram) in rabbits only a very slight augmentation of nembutal toxicity occurred, and this was also true for dogs. Our experiments are, of course, only partly comparable with Adriani's, since we studied only the acute effects of single doses. In this connection, it is interesting to note that W. L. M. King⁵ has been unable to find undesirable depression from ordinary sedative doses of barbiturates in pneumonia patients receiving sulfapyridine or sulfanilamide. We believe that the experimental results described in this publication justify the trial of sedatives in small doses in combination with sulfapyridine to alleviate irritating side effects of this drug upon the central nervous system.

SUMMARY

1. Death from intravenous lethal doses of sodium sulfapyridine in rabbits and dogs occurs during or after violent tonic or clonic convulsions.
2. Small doses of hypnotics, such as urethane or nembutal, can inhibit the convulsions and save life.

3. Subhypnotic doses of the urethane or nembutal are most effective; larger doses may cause death by adding to the secondary depressant action of sulfapyridine. Picrotoxin can overcome the effect of this summation.

4. Restlessness, nausea, and vomiting following large doses of sodium sulfapyridine in dogs can be completely eliminated by subhypnotic doses of nembutal.

5. The possibility of applying these observations to the alleviation of irritating side actions of sulfapyridine in man is discussed.

ADDENDUM.—After this paper was completed, corresponding work was done with sodium sulfathiazole. It was found that the lethal dose for dogs by intravenous injection lies between 200 and 1,000 mg. per kilogram. Thus it is less toxic than sodium sulfapyridine. We noticed, also, the absence of convulsions with doses below 800 mg. per kilogram, while sulfapyridine produces them with 500 mg. per kilogram. However, vomiting was observed with doses as low as 50 mg. per kilogram and in this respect it is more toxic than sodium sulfapyridine in dogs. On the other hand, most clinical reports indicate a lower incidence of nausea and vomiting with sulfathiazole. Encouraged by our results with nembutal in combating vomiting in dogs following sulfapyridine injection, we used this barbiturate also in combination with sodium sulfathiazole following the same technique as described above. Our optimal results were obtained if 20 mg. per kilogram of nembutal were injected intravenously simultaneously with 400 mg. per kilogram of sodium sulfathiazole. Three animals were used and all slept. No vomiting occurred. With dose levels of 200 to 500 mg. per kilogram of sodium sulfathiazole and 10 to 20 mg. per kilogram of nembutal we succeeded in suppressing the vomiting in about one-half the cases and decreasing its frequency in the other half without undue depression of respiration. Thus, principally, nembutal appears to exert the same effect in combination with sodium sulfathiazole as reported above with sodium sulfapyridine.

RECURRENCE IN PNEUMONIA

A CASE REPORT

JAMES M. RUEGSEGGER, M.D., AND SARAH LOUISE COCKRELL, M.D.
CINCINNATI, OHIO

RECOVERY from pneumococcic pneumonia is usually associated with the appearance of specific antibodies in the patient's blood stream. The immunity thus produced is not predictable either in duration or in amount, as adjudged by the conventional units; and despite this temporary immunity recurrent attacks are more frequent in this than in any other acute infectious disease. It has even been suggested that one attack of pneumonia predisposes another. The high historical incidence of previous attacks (20 per cent in our experience) tends to support this theory. However, if predisposition bears the same relation to type specificity as does immunity, a study of the types of pneumococci found in recurrent attacks of pneumonia lends the theory no support. In the four-year period 1935-1939, only four patients have been admitted to the Cincinnati General Hospital with recurrent attacks of pneumonia due to an homologous type of pneumococcus.¹ Of these pneumonias, two were due to type I pneumococcus, one to type II, and one to type VIII.

The influence of the carrier state on recurrences is not known but deserves further consideration. Finland and Winkler² collected a series of 57 cases from which they concluded that one attack of pneumonia did not confer permanently increased resistance against subsequent infections, even though of homologous types. (However, second infections rarely occurred within less than a year.) They also found that the duration and mode of termination, the distribution of the lesions and pneumococcic types were very similar in initial and recurrent pneumonias, and that bacteriemia occurred almost as frequently in second infections as in first. The later infections were found to differ only in two respects namely, that bilateral involvement was twice as frequent, and bronchopneumonia was encountered chiefly with the recurrences. These authors agreed that the acquisition of circulating type-specific antibodies and tissue immunity following one attack of pneumonia was only a temporary state and did not preclude recurrent pneumonia.

In experimental pneumonia of dogs, Coggeshall and Robertson³ have found that one infection confers increased resistance to a second, a resistance which lasts a varying number of months. This property is demonstrated by the fact that lethal dosages of organisms were used in producing a recurrent pneumonia at the site of the previous infection. With second infections, this injection was

*From the Department of Internal Medicine, Cincinnati General Hospital.
Received for publication, April 19, 1940.

made five days after the termination of the disease. If delayed, however, until two weeks after recovery, the dog died. After five or six attacks of pneumonia, the injection could be delayed three or four months with impunity. Lethal dosages injected fifteen to twenty-five days after the last infection into a previously uninvolved lobe resulted in death. Even with the greater dosages of organisms, the recurrent infections were milder, and the febrile course was briefer (two to three days). Bacteriemia dropped from 54 per cent in primary pneumonias to 5.6 per cent in recurrences.

In attempting to define the exact mechanism of this increased resistance, Coggeshall and Robertson found the leucocytic response prompt and adequate in both primary and recurrent infections. Excess of circulating antipneumococcic immune bodies varied greatly, some dogs apparently having none, though they recovered from their disease with rapidity.

The only marked difference that these authors found in primary and recurrent pneumonias was in the microscopic appearance of the lesions. Recurrent lesions in previously involved areas were invaded early by large numbers of macrophages, such as were found ordinarily in areas of resolution, and the pneumococci were found in either greatly diminished numbers or not at all. Large concentrations of interalveolar macrophages were to be found for five days following recovery; then they gradually diminished until, on the fifteenth day, they were no longer noticeable. Recurrent infections in previously uninvolved areas resembled primary infections produced with nonfatal doses of organisms, the macrocytic response occurring later than in the above.

Briefly, then, Finland and Winkler from their cases found no evidence of increased local or type-specific resistance. Coggeshall and Robertson, on the other hand, found a characteristic transitory change in the fixed tissue cells consisting of early localization of septal and perivascular cells and the rapid disappearance of injected organisms. For the period of its stay, this change gave increased resistance against a second infection.

In view of the preceding facts, it is interesting to speculate on the relationship of the several illnesses related in the following case report of a patient with recurrent type VIII pneumonia associated with meningitis.

CASE REPORT

A. R., a thirty-six-year-old colored woman, entered the Cincinnati General Hospital July 25, 1934. A right mastoidectomy was performed as an emergency operation. The laboratory reported a nonhemolytic gram-positive coccus cultured from the swab taken at operation; further identification was not attempted.

Three years later the patient was admitted to the Surgical Ward of the same hospital, where a colostomy was done July 15, 1937, to relieve a rectal stricture secondary to lymphogranuloma inguinale. Postoperatively, the patient developed a pneumonia in the right lower and middle lobes, with a white blood cell count of 23,600. No attempt was made to learn the etiology; treatment was symptomatic. A month later (on August 23) x-ray examination showed a localized area of density, 7 by 9 cm., which was interpreted as fluid in the lower posterior portion of the right chest. On direct examination of the aspirated pus, pneumococcus VIII was identified. The sputum also showed pneumococcus VIII on direct examination; the blood culture at this time, however, was negative. X-ray examination four weeks

later (September 21) showed a small amount of fluid still present, there being a definite fluid level. Two attempts at thoracentesis were unsuccessful. An x-ray examination of the chest taken just before dismissal on October 19, two and a half months after the original pneumonia, showed only evidence of thickened pleura. The right dome of the diaphragm was flattened and was adherent to the right lateral chest wall.

On February 13, 1939, the patient went to bed with influenza-like symptoms. Her husband stated that she had fever at this time and during the next few weeks she had seven or eight chills, several of them occurring during the week previous to admission. Headache (from which she had suffered since the mastoidectomy) became more severe, and was frontal in character. There was no vomiting and no earache. One week before entry (March 11), she developed a cough productive of a thin white sputum. By March 16 the severity of the cough had lessened. Her husband noticed that her hand strayed to the right side of head and neck, but she denied earache, merely stating that she had difficulty moving her head. Thirty-six hours before entrance to the hospital she stopped talking; her neck became stiff at that time and her eyes turned to the left.

Physical Examination.—On admission March 18, 1939, examination showed a critically ill, comatose, middle-aged negress in the opisthotonos position. Respirations were rapid and labored. Pulse rate was 160, of poor quality, but regular. Head and eyes were directed to left. The right corneal reflex was diminished, the left was absent; pupils were fixed to light. There was no facial asymmetry. The ears showed no evidence of recent infection. The neck was rigid. The heart was apparently normal. Chest findings were not remarkable except for dullness in the right lower axilla. The colostomy in the left lower quadrant seemed to be working well.

The tone of the right arm was questionably greater than that of the left. Focal tremors occurred in the right arm and leg, occasionally spreading to the left. Reflexes were diminished in the arms, and were normal in the legs. Plantar responses were absent. Brudzinski's and Kernig's signs were present.

Accessory examinations showed a leucocytosis of 21,350, with a definite shift to the left. Lumbar tap yielded cloudy fluid under an initial pressure of 110 mm.; of the 15,000 white blood cells, 98 per cent were polymorphonuclear leucocytes. Pneumococci type VIII were seen on direct examination of the spinal fluid. A blood culture showed countless colonies of pneumococcus VIII per cubic centimeter. A culture taken from the throat also showed pneumococcus VIII in moderate numbers.

History Course.—During the succeeding thirty-four hours the patient was given 17.5 Gm. of sodium sulfapyridine intravenously and fluids subcutaneously without any noticeable change in the course of the illness. Despite levels of sulfapyridine of 17.7 mg. per cent in the blood and 14.8 mg. per cent in the cerebrospinal fluid, and a sterilization of the blood stream, she died.

Autopsy revealed acute endocarditis, involving the mitral and tricuspid valves; acute purulent leptomeningitis; old organized lobar pneumonia of the right upper lobe; elephantiasis of labia majora; moderate rectal stricture; double-barreled colostomy; evidence of old right mastoidectomy; old right obliterative pleuritis; and toxic changes of the viscera.

Pneumococci VIII were identified from the spinal fluid and from the right upper lobe lung tissue on direct examination. Blood culture taken twelve hours post mortem showed no growth. Blood broth culture of the tricuspid vegetation after two weeks' preservation in 10 per cent formalin yielded pneumococcus VIII. Only the tricuspid vegetation was cultured, the mitral vegetation being saved for histologic inspection.

COMMENT

Careful bacteriologic study was not made of the original organism isolated from the mastoid. However, since the description of the organism permits the consideration of a pneumococcus, it might be noted here that pneumococcus VIII is not infrequently found in the ear and paranasal sinuses.

Three years later the patient had a clinically atypical pneumonia due to pneumococcus VIII; this was complicated by empyema. Eighteen months later she was readmitted with a pneumococcus VIII infection of the lung, endocardium, and meninges. It is interesting to note that this second pulmonary infection did not involve the previously involved lobes, raising the speculation that there may have been a residual tissue immunity within the lung⁴ from the first infection, despite the apparent breakdown in general immunity. Unfortunately, no bacteriologic or immunologic studies were made during intervals of apparently good health. But in view of the fact that pneumococcus VIII was found in the patient's sputum and pleural fluid at a time when she had no clinical evidence of pulmonary disease, it seems a not unfair assumption that she remained a carrier after she had recovered from the acute pneumococcal pneumonia. The implication must be that she erected sufficient immunity defenses to recover from the pneumonia and to hold the organism in abeyance even though it was still present in the respiratory tract and pleural cavity.

Finland and Tilghman,⁵ studying pneumococcic infections in families and other closely-knit groups, found that healthy carriers of disease-producing pneumococci may develop type-specific antibodies. This raises the question whether the carrier state may be desirable in convalescent pneumonias; or whether the repeated or continuous antigenic effect of the saprophytic organisms depresses the formation of antibodies, a condition frequently seen in hyperimmunized horses. This supposition scarcely seems plausible in view of the infrequency of homologous recurrences and the relatively high incidence of carriers among convalescents for varying periods following the acute infection.

Despite our incomplete knowledge concerning the pathogenesis of pneumococcal pneumonia and immunity to it, the carrier state appears to constitute a potential danger not only to others, but also to carriers, and as such should be a point of attack in pneumonia programs.

SUMMARY

A case of recurrent pneumonia due to the homologous type of pneumococcus is reported, with the implication that it probably represents a self-infection.

FURTHER OBSERVATIONS ON THROMBOCYTOPEN*

FRANK OTENASEK, M.D., AND FERDINAND C. LEE, M.D., BALTIMORE, MD.

FROM the spleens of three successive persons with idiopathic thrombocytopenic purpura a substance was extracted which reduced the number of platelets in the circulating blood of rabbits. This substance was called thrombocytopen, and was described in detail in 1938.¹ In the subsequent ten months, only one other patient suffering with the disease has come to operation in the hospital. The extract from the spleen of this patient not only corroborated and substantiated the observations made with the former preparations, but it also opened up new paths of investigation. In addition, four more control spleens have also been extracted and tested.

MATERIAL AND METHOD

CASE.—A. W., a white married woman, aged 24 years, was admitted to the Johns Hopkins Hospital on September 17, 1938, complaining of excessive bleeding. Her family history revealed a maternal aunt who had "purpura," but was successfully treated with snake venom. Her past history is of little interest. Her menstrual periods were always regular, occurring every twenty-six days, and lasting seven days, with variable flow. About five years before admission she began to notice hemorrhages around her gums and became aware of the fact that she bruised easily. A year and a half later she was delivered spontaneously of a full-term normal child. The exact amount of blood loss at that time is unknown, but the patient was transfused with 500 c.c. of blood and remained well for six months, after which time the bleeding recurred. Three years ago moccasin venom was started (dosage unknown) and continued for six months, with some alleviation of symptoms. Two months after cessation of treatment the hemorrhages recurred. One year ago venom therapy was begun once more and was continued for two months without benefiting the condition. In view of the unfavorable response, the patient was given a 500 c.c. blood transfusion. In December, 1937, deep x-ray therapy over the spleen was instituted, 1,750 r. in air being given anteriorly, and 750 r. posteriorly, over the splenic region. Following this treatment she was considerably improved until July, 1938, when weakness returned and petechial hemorrhages once more appeared. In the two months prior to her admission she was given three 500 c.c. blood transfusions as well as liver extract. Since the onset of her illness she has had many fainting attacks which were usually followed by an exacerbation of her purpura. The platelet count on August 4, 1938, was 170,000, and on August 30, it was 180,000. Physical examination of the patient was essentially negative. There were no evidences of hemorrhage in the skin or gums. The spleen was not palpable. Blood studies made on September 19 revealed leucocytes 5,050, hemoglobin 93 per cent, red blood cells 4.73 million, and platelets 80,000. The clotting time was normal, the bleeding time was eleven minutes. The clot was nonretractile. The tourniquet test was negative, as was also the routine Wassermann on the blood serum. On September 20, splenectomy was performed by Dr. Warfield M. Firor. The patient recovered from the operative procedure satisfactorily. There was no excess of bleeding either at operation or afterward. The platelet count three hours after operation was 166,000. During the period of her stay in the hospital it remained around 150,000. The bleeding time was less than four and one-half minutes. The patient was discharged on October 3, symptomatically well.

*From the Surgical Hunterian Laboratory of the Johns Hopkins University, Baltimore.
Received for publication, April 20, 1940.

The spleen weighed 95 Gm. and looked grossly normal. Microscopically there were many large Malpighian corpuscles with germinal centers. Final pathologic diagnosis: spleen showing nonspecific changes (thrombocytopenic purpura).

The preparation of the spleen began on the day of operation, when the organ was ground up and placed in twice its volume of reagent acetone. One month later, on October 25, one-half of the extract was removed and filtered, and evaporation of the acetone was carried out by reduced pressure under a Bell jar. This step in the preparation of the extract differed from the previously published method in which distillation of the acetone was carried out under reduced pressure with the application of some heat. It was thought that even a small amount of heat might affect the potency of the preparation, and in fact a more potent product did result when heating was omitted.

When evaporation was complete, the usual dark brown, gummy residue was left. This was suspended in 100 c.c. of distilled water. The dilution of this extract was, therefore, twice that obtained from previous spleens, since formerly the same amount of distilled water was added to the acetone-extracted material from an entire spleen.

The extract was injected in amounts varying from 0.5 to 10 c.c. into 10 rabbits, all of which died in periods ranging from one hour to twenty-four hours after the injection. In the animals which survived more than four hours after injection, it was noted that the platelet count fell significantly. The direct method of counting platelets with the fluid of Rees and Ecker was used, and every count was controlled by the indirect blood smear procedure.

The remainder of the extract was now run through a Seitz filter and further injections were made. Subsequently all extracts were Seitz filtered before injection.

RESULTS

Experiment 1. A male rabbit (R-13), weighing 2.4 kg., was injected intravenously with 1 c.c. of the extract from patient A. W. on December 28, 1938. The blood platelets fell from 610,000 to 283,000 in six hours, and hovered in the neighborhood of 280,000 during the subsequent eighteen hours. Another 1 c.c. of the extract was injected on December 29, the platelets varying from 213,000 to 280,000 during the next twenty-four hours. On December 30 the platelets began to fall to lower levels without further injection, and reached the low count of 94,000 approximately fifty-four hours after the first injection. By the morning of the following day the platelets had risen precipitously, reaching a high count of 6,029,000. Many huge, abnormal appearing platelets were seen. Smears showed enormous numbers of platelets at this time. During the period of study the red blood cells did not vary significantly from the normal. Leucocytosis was practically constant, the white blood cell count being in the neighborhood of 20,000, with an excess of adult polymorphonuclear forms. On January 1 the animal died. Autopsy revealed no hemorrhages. There was patchy consolidation of both lungs. Sections of the femur bone marrow revealed hyperplasia of the myeloid elements. No abnormalities could be found in the megakaryocytes.

Experiment 2. On January 25, 1939, 1 c.c. of the same extract was injected into another male rabbit (R-17), weighing 2.2 kg. A control specimen of bone marrow had been removed from this animal by biopsy nineteen days previously. Table I shows behavior of platelets after injection. The white blood cells had risen from an original count of 4,950 to nearly 15,000 on the second day, and gradually fell to a normal level three days later. The red blood cell count did not vary significantly from an original count of 4.78 million. On February 2, 1939, the animal died. Autopsy revealed patchy consolidation of lungs. Sections of the spleen revealed small foci of myeloid tissue with disproportionately great numbers of megakaryocytes, and these cells appeared in the liver as well (Fig. 1). There was no evidence of platelet formation in the lungs. The femur bone marrow showed no detectable abnormalities either in the number or in the morphology of megakaryocytes.

Experiment 3. On February 23, 1939, a male rabbit (R-15), weighing 1.8 kg., was injected with 1 c.c. of the extract. A bone marrow biopsy had been made six weeks previously. The platelets fell characteristically (Table I) from the preinjection level of 628,000 to a low of 55,000 three days later. Eight days after the original injection the platelets had risen

only to 217,000, and the animal was sacrificed. No noteworthy changes were found in the megakaryocytes of the femur marrow, but the spleen again showed many megakaryocytes, the liver a few. The lungs and other organs were normal.

Meanwhile, on February 1, 1939, the second half of the acetone extract from the spleen of A. W. was prepared for use by evaporation of acetone and suspension of the residue in distilled water. This was not used, however, until March 20, 1939, after an interval of seven weeks. It had, however, been kept in the refrigerator at a temperature of about 40° F.

TABLE I

Rabbits R-15 and R-17 received intravenously 1.0 c.c. of the splenic extract, while rabbit R-29 was given 2.0 c.c. Rabbit R-26 served as a control.

HOURS AFTER INJECTION	PLATELETS $\times 10^5$			
	R-17	R-15	R-26	R-29
0	6.52	6.28	6.23	5.71
1	5.09	5.59	-	-
2	4.08	2.42	-	-

168	-	2.17	5.58	-
192	-	-	5.81	-
216	-	-	6.92	-

Experiment 4. On March 20, a male rabbit (R-19), weighing 2.1 kg., was given two injections of 0.5 c.c. each of this second preparation of extract from A. W., without a significant change from the preinjection level of 620,000 platelets. The following day another 1.0 c.c. was given, and the platelets reached a low of 453,000 three hours after the injection. For the next three days the platelets varied between 252,000 and 550,000, when another 1 c.c. of extract was injected. They fell again to 232,000 and remained at 200,000 to 414,000 until March 27, when the platelet count reached a high of 729,000. Two cubic centimeters of the extract were then injected, and the platelets rose to 1,624,000 and then to 3,629,000 two and six hours, respectively, after injection. Mostly large, abnormal platelets were seen. By the next morning the platelets had fallen precipitously to 332,000, then rose rapidly and steadily to 7,805,000 at 4:00 P.M. and to 9,450,000 at 11:30 P.M. Smears made at this time showed great masses of platelets such as those illustrated by Bunting.² The white blood cell count at this time was 20,000 and the red blood cell count was 5.02 million. There was nothing unusual about the smear except for the platelets. On the following day (March 29) the platelets, which were 848,000 in the morning, had reached 3,065,000 sixteen hours later. A maximum leucocyte count of 32,150 was found at this time.

For the next two days the platelets varied between 204,000 and 821,000, and the animal was killed. Post-mortem histologic sections of organs revealed no detectable abnormalities. Differential counts were attempted on megakaryocytes of femur marrow, but no significant change was noted when compared with control sections.

Experiment 5. Another male rabbit (R-27), weighing 2.4 kg., was treated exactly as was rabbit R-19 and reacted in the same way. Control biopsies of spleen and bone marrow had been taken three weeks before injections were begun, but no anatomic abnormalities could be made out in the post-mortem sections.

Experiment 6. To eliminate the possibility that the many small bleedings necessary for counting platelets were responsible for the changes in the blood picture of all the animals or

for the presence of megakaryocytes in the spleen and liver of two of the earlier animals, a control rabbit R-26 was bled in amounts varying from 0.2 to 1.0 c.c. three times daily for ten days (Table I). The platelets varied from 692,000 to 475,000, while the other formed elements of the blood did not vary significantly. The animal was sacrificed on the tenth day. Histologic sections of femur marrow and spleen made post mortem did not differ from biopsy specimens taken from the same animal three weeks before the bleedings were begun.

Animals used for all subsequent experiments underwent biopsies of spleen and femur bone marrow at least three weeks before any injections were made.

Fig 1—Section of spleen from rabbit R-17 showing a large number of megakaryocytes which normally are not present in the spleen (H. & E. $\times 7$).

Experiment 7. On April 3, 1939, a male rabbit (R-29), weighing 1.7 kg., was injected with 2.0 c.c. of the second half of the extract (Table I). The platelets fell from a control level of 571,000 to 78,000 in fifteen hours, and for the next five days varied from 70,000 to 321,000 without further injection. Then they slowly began to rise until on April 9, six days after the injection, the count had risen to a normal of 625,000, and the animal was killed. Sections of the spleen showed occasional megakaryocytes, but no abnormalities could be detected in other organs.

Experiment 8. Another male rabbit (R-30), weighing 1.8 kg., was injected with 2.0 c.c. of extract on April 11, 1939. The platelets fell from a normal of 545,000 to a low of 161,000 on the day of injection. On the following day they rose from 1.06 million to 2.86 million. This same day, eight hours after the count of 2.8 million, the platelets had fallen to 172,000. On the following day (April 13) they rose from 133,000 to 576,000, and the animal was killed. No significant post-mortem histologic findings were observed.

Experiment 9. A female rabbit (R-31), weighing 3.3 kg., was now used. It seemed evident that the extract was losing potency, so 2 c.c. were injected on April 25 without effect, and another 2 c.c. were given sixteen hours later. The platelets then fell to 107,000. They were around 200,000 for two days, when 2.0 c.c. were again injected without further

effect. Subsequently 2.0 c.c. and then 4.0 c.c. were injected separately in the next four days, but the platelets continued to remain around 200,000. The animal was then sacrificed. Sections revealed no abnormalities.

Experiment 10. In those animals studied during May, 1939, as much as 16 c.c. of the extract given over a two-day period in doses of 8 c.c. succeeded in bringing platelets down only to 191,000. It became even more evident that the extract was losing strength.

Experiment 11. On May 29 a male rabbit (R-16), weighing 2.6 kg., was injected with 8 c.c. of the extract. Platelets fell only to 421,000 fifteen hours after injection. The last 20 c.c. of the extract were then injected. The following day the platelets were counted at 419,000 and slowly rose to 592,000. The animal survived and subsequent counts were normal.

CONTROL EXPERIMENTS

Spleens removed at operation from four patients suffering with conditions other than thrombocytopenic purpura were extracted and studied. Three of these were spleens removed for Banti's syndrome, while one was a normal spleen removed because of rupture as a result of trauma. The extracts were prepared in the manner described, but on injection into rabbits of amounts up to 40 c.c. no significant alterations in the blood platelet level were produced.

COMMENT AND DISCUSSION

The preparation of thrombocytopen, as described in this report, presents two significant differences from that previously mentioned.¹ In the first place, removal of the acetone from the extract was accomplished by distillation under reduced pressure with the application of a small amount of heat. This method, however, presented two difficulties. First, as more and more acetone was distilled off, the residue became thicker and thicker, and it was only by great effort and careful regulation of applied heat that the material was prevented from bubbling up through the distillation system. There was no doubt that some of the extracted material remained in the system. Second, it was not known whether or not thrombocytopen was heat stable, and hence some of its potency in the early extracts might have been lost by heating. With the new method of removal of acetone by evaporation under reduced pressure in a Bell jar, it was possible to obtain a residue rich in thrombocytopen to which no heat had been applied.

The second difference in preparation was in use of the Seitz filter. Although ordinary sterile precautions were taken, and although the extract was always kept in the refrigerator, bacterial and other contamination necessarily occurred sooner or later. It was as an added precaution, then, that Seitz filtration was carried out before injections. This procedure ruled out the possible effect of specific³ as well as nonspecific organisms.

The action of the present extract differed somewhat from that previously reported. For the most part, the production of thrombopenia followed the pattern established in the early experiments of Troland and Lee, but it was more prolonged, lasting in the case of rabbit R-17 seven days after the injection of 1 c.c. Furthermore, the effect of the extract was variable in that in some cases a secondary thrombocytosis was encountered. Whether this reaction was compensatory to the primary diminution in the platelet level, or whether it indicated some stimulatory effect of the extract on the thrombopoietic system, could

not be ascertained. Elevation of the blood platelet count above the normal has been observed experimentally under many different conditions. Bedson⁴ noted prolonged thrombocytosis following splenectomy in rabbits. In the same species thrombocytosis has been observed following injections of bacillus thrombo-cytogenes,³ following experimental productions of subcutaneous abscesses,⁵ and after the administration of certain drugs such as pyrodine,^{6, 7} trypan blue,⁷ phenylhydrazine,⁸ turpentine and saponin.² Inhalations of carbon monoxide and carbon dioxide by rabbits also resulted in temporary increase in the number of platelets.^{9, 10} The effect of ultraviolet rays in raising the platelet count has been demonstrated by Steiner and Gunn¹¹ and by Toyoda.¹² Bedson⁴ and Koster¹³ described thrombocytosis after "blockade" of the reticulo-endothelial system with India ink. Clinically, thrombocytosis has been observed frequently following splenectomy, and platelet counts as high as 5 or 6 million have been reported.^{14, 15}

In none of the reports in the literature has thrombocytosis approached a platelet level of 9,450,000, as observed in rabbit R-19. In this rabbit, and in the other animals displaying unusually high platelet counts, abnormally large and irregularly sized platelets were frequently seen in the counting chamber and in smears. This phenomenon has been previously described by Bedson¹⁶ and others.

No light has as yet been thrown on the precise manner in which thrombo-cytopen exerts its influence on the experimental animal. In two of the earlier animals, R-17 and R-15, in which the platelet counts were maintained at low levels for seven and eight days, respectively, post-mortem sections of the spleen showed megakaryocytes in great abundance. That they may occur normally in small numbers in adult rabbits is pointed out by Pianese.¹⁷ Definitely increased numbers were noticed by Bunting,¹⁸ and by Firket and Campos,¹⁹ following intravenous injection of saponin in rabbits. Pugliese²⁰ noted the same phenomenon in hedgehogs following repeated bleedings. To rule out the possibility that the presence of megakaryocytes in the spleens of rabbits R-17 and R-15 was due to the repeated small bleedings necessary for blood studies, another animal, rabbit R-28, was subjected to venepuncture and removal of blood in like quantities for a period of ten days. This animal received no thrombocytopen, and sections made from the spleen and bone marrow removed at autopsy could not be distinguished from control sections obtained from biopsy specimens one month before the experiment began. Platelets in this animal were counted at least three times a day during the ten-day observation period. They were found to vary from 475,000 to 692,000.

The prolonged effect of thrombocytopen in some of the experiments being reported suggested the possibility that the extract might affect the megakaryocytes directly. The condition of the bone marrow and megakaryocytes in idiopathic thrombocytopenic purpura has never been adequately settled. Jedlička and Altshuller,²¹ and Papp and Antognini²² noted morphologic changes in the megakaryocytes of bone marrow in several cases of purpura. Willis²³ studied megakaryocytes during different phases of thrombocytopenic purpura. He noted no variations in megakaryocytes, and saw no sign of platelet formation in severe forms of the disease. In 6 cases of thrombocytopenic

purpura studied by Lawrence and Knutti²⁴ megakaryocytes were normal in number and diminished in 2. Vogel, Erf, and Rosenthal²⁵ observed no variations in quantity or quality of megakaryocytes. In our own studies no numerical or morphologic changes could be detected in the bone marrow giant cells, either in animals whose platelets had suffered a reduction in number, or in those whose platelets had reached very high levels. Observations made by supravital technique or on fixed material stained by Wright's or hematoxylin and eosin failed to reveal significant alterations from the bone marrow picture shown in biopsy material taken before experimental injections of thrombocytopen were made. The mode of action of the extract is, therefore, still unsettled.

It appears from the experiments that the potency of the extract, as preserved in aqueous solution, diminishes with time. The earlier experiments from December to early April (three to seven months after splenectomy) showed an activity of the extract which was fairly uniform in that a given dose produced a diminution in platelets which was sometimes followed by a thrombocytosis. Later, however, gradually increasing doses were required, and finally even large doses had no effect. Whether this apparent decrease in potency could have been prevented by keeping the extract either in acetone or in the dry state was not determined.

In recent months a number of investigators²⁶⁻³⁰ have published reports dealing with failure to isolate thrombocytopen from spleens of patients with thrombocytopenic purpura. It is impossible to explain this apparent disparity in results. A point of interest arises, however, in the fact that many spleens extracted by the afore-mentioned workers were significantly heavier than those of Troland and Lee¹ or the one in the present report. The question arises whether there may not be several forms of idiopathic thrombocytopenic purpura depending on the size of the spleen and the presence or absence of an extractable platelet-reducing substance. Even clinically, a large spleen has raised doubts regarding the correct diagnosis of thrombocytopenic purpura according to Wiseman.³¹ Hobson and Witts³² recently found some platelet-reducing activity in the extract of a spleen from a case of purpura hemorrhagica.

SUMMARY

A preparation of thrombocytopen from a patient with idiopathic thrombocytopenic purpura caused reduction of blood platelets in rabbits. In some cases a marked thrombocytosis followed, and in several experiments large numbers of megakaryocytes could be found in the spleens of the animals studied.

Four more control spleens, extracted in a similar manner, proved to have no effect on blood platelets.

The potency of an aqueous solution of thrombocytopen diminishes with time.

THE EFFECT OF GOLD SODIUM THIOMALATE ADMINISTRATION ON THE BACTERIOSTATIC PROPERTIES OF THE SERUM IN PATIENTS WITH RHEUMATOID ARTHRITIS*

EDWARD F. HARTUNG, M.D., AND JOYCE COTTER, B.A.
NEW YORK, N. Y.

CLINICAL reports on the use of gold salts administered parenterally for the treatment of rheumatoid arthritis are becoming more numerous, and the reported therapeutic results are more favorable. Hartfall, Garland, and Goldie¹ summarized the largest series (900 cases of all types of arthritis) in 1937. They obtained cures or striking improvement in 80 per cent of their cases of rheumatoid arthritis. The German, French, and English literature is now fairly voluminous, and, on the whole, favorably inclined toward this method of treatment, especially when confined to its use in rheumatoid arthritis.

In the United States the reports on the use of gold salts in arthritis are not as numerous. They include those by Sashin and Spanbock,² Oren,³ Phillips,⁴ and Snyder, Traeger, and Kelly.⁵ Our own experience with the use of gold salts is somewhat comparable to the favorable reports in the literature. We have observed that gold salt therapy gives a higher percentage of improvement than any form of therapy yet used by us in the treatment of rheumatoid arthritis. Our own results approximate those of Hartfall and associates to the extent that 60 per cent have shown marked improvement. We cannot at present report the percentage of cures, because it is our opinion that patients with arthritis should be followed for a minimum of five years before they are reported as cured, and none of our patients treated with gold salts have been under our observation that long.

In the past, and at present, a variety of gold compounds, in aqueous or oil solution, have been used by investigators. Our own clinical observations are limited to the use of aqueous gold sodium thiomalate, administered subcutaneously. In the usual case of rheumatoid arthritis, according to the schedule we have gradually developed, this is injected once a week in 5, 10, 25, and occasionally 50 mg. doses, until a total of 1 Gm. has been given. After an interval of twelve weeks, the entire course is repeated. It is sometimes deemed necessary to give a third course. Toxic reactions are rather frequent. Minor difficulties are encountered in at least one-half of the patients treated, and serious reactions in fully 15 per cent.

OBJECTIVE

Our objective in the investigation reported here was to study the bacteriostatic properties of the serum before and after the parenteral administration

*From the Arthritis Clinic and Department of Bacteriology, New York Post-Graduate Medical School and Hospital, Columbia University, New York.
Received for publication, April 22, 1940.

of gold salt in varying amounts. We were also interested in observing the effect of gold salt administration on the agglutinin titers. Such studies might throw some light on the serologic and pharmacologic action of gold salt, and suggest a hypothetical explanation of its apparent effectiveness in the treatment of rheumatoid arthritis. This and other studies now under way might also lead to a better understanding of the all too frequent toxic effects and point the way to methods of avoiding them.

MATERIALS

In planning a study of the bacteriostatic properties of serum before and after gold salt administration, an organism had to be arbitrarily selected against which to study these effects. It is generally believed that rheumatoid arthritis is a disease of infectional origin. However, the causative agent has never been conclusively demonstrated. The hemolytic streptococcus has been suggested, but on no firmer grounds than that a greater percentage of sera from patients with rheumatoid arthritis show agglutinins in high titers for hemolytic streptococci than do sera from patients with osteoarthritis, or from normal subjects.⁶ In our studies we used a beta hemolytic streptococcus (strain Greene) isolated from an acute mastoid infection. We do not in any sense imply that this organism is related to the etiology of rheumatoid arthritis. Other common laboratory microorganisms were used in various parts of the investigation. These will be detailed in the appropriate place.

The gold salt used uniformly throughout these experiments was an aqueous solution of gold sodium thiomalate administered as already outlined. It contains 50 per cent metallic gold. In addition, we were interested in observing the bacteriostatic effects following the administration of colloidal gold, a 1 per cent metallic gold in colloidal suspension, and bismuth subsalicylate, 10 per cent in oil.

The persons on whom we investigated these effects were all patients with typical rheumatoid arthritis. All of them exhibited the usual clinical and x-ray findings, together with various degrees of elevation in the sedimentation rate. Most of them were ambulatory.

TECHNIQUE FOR DETERMINING BACTERIOSTASIS

A seventeen-hour culture of hemolytic streptococcus, strain Greene (a beta strain, Group A) grown in 1 per cent dextrose meat infusion broth was diluted 1:5,000. One five-hundredth cubic centimeter (0.05 c.c.) of this dilution was added to 1 c.c. of the serum to be tested. This amount of culture usually produced from 5 to 25 colonies. The inoculated serum was then incubated at 37° C. for forty-eight hours.

The growth in the inoculated serum was estimated as follows:

A. One five-hundredth cubic centimeter (0.05 c.c.) of the inoculated serum was plated in blood (1 c.c.), agar (10 c.c.).

B. A 1:1,000 dilution of the inoculated serum was made. One five-hundredth cubic centimeter (0.05 c.c.) of this dilution was likewise plated in blood agar as above.

After twenty-four hours' incubation the colony growth on the plates was counted and the growth was estimated in colonies per cubic centimeter of original culture. This was done in the case of the undiluted serum by multiplying the number of colonies on the plate by 20, and in the case of the diluted serum, by 20,000.

All dilutions were made with stock 1 per cent dextrose meat infusion broth, dilutions with normal saline being avoided because of the known bacteriostatic effect of saline on the growth of streptococci in vitro. All tests were done in duplicate.

RESULTS

Experiment 1.—Normal controls. The sera of 20 laboratory workers, all in good health, were studied for their bacteriostatic effect on hemolytic streptococcus (strain Greene), and their agglutinin titers against this organism were determined. Bacteriostasis was negligible (Table I) except in occasional instances (Cases Nos. 3, 4, 5, 8, 10, 19, and 20). Some of these patients had recently received, or were receiving, vaccines or bacteriophage against colds. The agglutinin titers likewise were found to be about as has been usually observed in normal controls when a beta-hemolytic streptococcus was used as the antigen.

Experiment 2.—The bacteriostatic effect on hemolytic streptococcus, strain Greene, of serum taken before and after the administration of gold sodium thiomalate. The bacteriostasis was studied in patients with rheumatoid arthritis before the gold sodium thiomalate was given, and after varying amounts had been administered parenterally, in divided doses, according to the schedule suggested above for the routine treatment of these patients. It was found (Table II) that the initial bacteriostasis was about as in the normal controls.

After varying amounts of gold salt were administered there was a marked increase in the bacteriostasis in every instance, even after as little as 60 mg. had been given.

13	15	Unsatisfactory	215	250
17	205	50	250	50
20	240	110	921	55

Table III reports the bacteriostatic properties of the serum in intermediate stages of the administration of gold salt. In these subjects, where gold salt had been given before the initial tests were done, the initial bacteriostasis was greater than normal (except in Cases 3 and 8, where only 15 and 85 mg. had been given) and was increased after more gold salts had been administered subsequent to the initial determination. It will be observed that the bacteriostasis indeed was roughly proportional to the amount of gold salt given. In general, the maximum bacteriostasis seen in these experiments was observed after 147 to 155 mg. had been given, and it did not materially increase even after many times these amounts of gold had been administered.

Experiment 3.—We were interested in observing the effect of gold sodium thiomalate on the agglutinin titers of the serum against hemolytic streptococcus (strain Greene). Initial determinations were done and repeated after varying amounts of gold salt had been given. In general, no consistent changes were observed (Table IV).

*Vaccines previously administered.

Experiment 4.—The effect of the continuing administration of gold salt on the bacteriostatic power of the serum. The subjects received weekly injections of gold sodium thiomalate, and the bacteriostasis was determined after varying amounts had been given. From a review of Table V, it is observed that the bacteriostasis in each case increased in rough proportion to the total

amount of gold salt given. In Case 2, for reasons not obvious, the original bacteriostasis was greater than usual in the controls; and after 50 mg. of gold salt, it was less than at the initial determination. After 115 mg., however, marked bacteriostasis was found, and after 155 mg. the bacteriostasis was still more pronounced.

TABLE VI

CHANGES IN THE BACTERIOSTATIC POWER OF THE SERUM AFTER STOPPING ADMINISTRATION OF GOLD SODIUM THIOMALATE

CASE NO.	DATE	AMOUNT OF GOLD SALT GIVEN (MG.)	BACTERIOSTASIS (COL./C.C.)
6	8/24/39	0	α 1:1,000 dilution
	9/21/39	125	2,024
	10/31/39	200	202

	10/21/39	310	160
	Injections of gold salts stopped		
	4/ 4/40		α 1:1,000 dilution
20	6/28/39	260	110
	11/20/39	921	55
	Injections of gold salts stopped		
	2/15/40		142,000,000

Experiment 5.—Changes in the bacteriostatic power of the serum after stopping the administration of gold sodium thiomalate. In this experiment, 3 patients with rheumatoid arthritis received 200, 310, and 921 mg., respectively, of the gold salt in divided weekly doses over varying lengths of time. Marked bacteriostasis resulted. In each case the administration was then stopped for important clinical reasons. After varying intervals of time had elapsed, the bacteriostasis was again determined and was found to have returned to the levels usually found in normal controls. In other words, after the gold salt had been withheld from these patients for from three to six months, the previously observed bacteriostatic power of their serum was found to be absent (Table VI).

TABLE VII

EFFECT OF COLLOIDAL GOLD ADMINISTRATION ON THE BACTERIOSTATIC POWER OF THE SERUM

CASE NO.	COLLOIDAL GOLD GIVEN BEFORE INITIAL TEST	INITIAL BACTERIOSTASIS (COL./C.C.)	TOTAL COLLOIDAL GOLD GIVEN (C.C.)	FINAL BACTERIOSTASIS
101	0	α 1:1,000 dilution	6.0	α 1:1,000 dilution
102	0	α 1:1,000 dilution	14.8	α 1:1,000 dilution
103	0	α 1:1,000 dilution	11.5	α 1:1,000 dilution
104	0	3,000,000	3.6	α 1:1,000 dilution

Agglutinin titers show no change throughout.

Experiment 6.—Effect of colloidal gold administration on the bacteriostatic power of the serum. We were curious to see whether preparations of colloidal gold would induce bacteriostasis, as was observed after the administration of gold sodium thiomalate. In 4 patients a preparation of 1 per cent colloidal gold was administered parenterally in divided weekly doses. In

Case 102 a total of 14.8 c.c. was given. This latter was equivalent to 280 mg. of gold sodium thiomalate in terms of metallic gold content. From Table VII, it is obvious that no bacteriostasis was induced in this case or in any other case under observation.

Experiment 7.—Bacteriostasis before and after the parenteral administration of bismuth subsalicylate, 10 per cent in oil, in divided weekly doses. The initial bacteriostasis was determined, and again after varying amounts of bismuth had been administered. Some bacteriostasis was produced by this method, but not in amounts comparable with that following the administration of gold salt (Table VIII).

Experiment 8.—The in vitro effect of varying dilutions of gold sodium thiomalate on the growth of hemolytic streptococcus, strain Greene. Varying dilutions of gold sodium thiomalate in 1 per cent dextrose beef infusion broth were prepared. The first tube contained 10 mg. of gold sodium thiomalate in 1 c.c., and the others contained lesser amounts, as recorded in Table IX. To each dilution was added 0.05 c.c. of 1:5,000 dilution of an eighteen-hour culture of hemolytic streptococcus (strain Greene). After forty-eight hours' incubation the amount of growth was determined.

This experiment was repeated many times with rather consistent findings. Two typical results are reported in Table IX. In general, it was observed

that there was no growth in the tubes containing from 10 to 0.0001 mg. of gold sodium thiomalate, after which moderate and then luxuriant growth was observed.

Six other organisms were arbitrarily selected and subjected to identical in vitro studies. The results were similar to those obtained when using hemolytic streptococcus, strain Greene, although less susceptibility to gold was shown by some of these organisms. The amount of bacteriostasis was roughly proportional to the concentration of gold salt present in the dilution. The details of these findings are summarized in Table X.

TABLE X

TABLE XI

IN VITRO EFFECT OF VARYING DILUTIONS OF GOLD SODIUM THIOMALATE IN 50 PER CENT WHOLE HUMAN BLOOD ON THE GROWTH OF HEMOLYTIC STREPTOCOCCUS, STRAIN GREENE

DILUTIONS OF GOLD SALT (MG./C.C.)	GROWTH OF HEMOLYTIC STREPTOCOCCUS, STRAIN GREENE, AFTER 48 HOURS' INCUBATION	
	COL./C.C. EXPERIMENT 1	COL./C.C. EXPERIMENT 2
10.0	7,720	2,550
1.0	350,000	220,000
0.1	α 1:1,000	α 1:1,000
0.01	α 1:1,000	α 1:1,000
0.001	α 1:1,000	α 1:1,000
0.0001	α 1:1,000	α 1:1,000
0.00001	α 1:1,000	α 1:1,000
0.000001	α 1:1,000	α 1:1,000
0.0000001	α 1:1,000	α 1:1,000

When whole blood was added to the extent of 50 per cent of the final dilutions in these in vitro studies, the bacteriostatic power of the gold salt was destroyed in all except the first two tubes (Table XI).

DISCUSSION

In 1890 Koch,⁷ and later DeWitt and Sherman,⁸ reported that gold cyanide in dilutions of 1:2,000,000 inhibited the in vitro growth of tubercle bacilli.

Shortly after this, White⁹ reported favorable results following the hypodermic administration of a combination of gold and manganese in the treatment of tuberculosis. Somewhat later, Mayer,¹⁰ Spiess and Feldt,¹¹ Mollgaard,¹² and others reported on this form of therapy in tuberculosis. In 1928-1929 Umber¹³ in Germany and Forestier¹⁴ in France almost simultaneously applied the use of gold salts to the treatment of rheumatoid arthritis, because of the hypothetical association of rheumatoid arthritis and tuberculosis.

One explanation easily suggested for the apparent effectiveness of gold salts administered parenterally in certain infections was that they acted in the body by exerting a direct bacteriostatic effect. Since, however, the *in vitro* inhibition of the growth of tubercle bacilli by gold salts was destroyed in these early experiments by the addition of human or animal blood, it was felt that the favorable results were not due to a direct bacteriostatic effect, but to the stimulation of some unexplained defense mechanism in the patient, most probably the reticulo-endothelial system. Our own observations also showed the *in vitro* loss of bacteriostatic effect when blood was added to the broth dilutions, due possibly to a precipitation of the gold to an insoluble and inert form. Such inactivation may not occur, however, when the salts are injected parenterally.

Certainly there is no evidence that gold salts produced bacteriostasis by stimulating any of the known defense mechanisms of the body. Our observations show that the agglutinin titers, at least for the particular streptococcus used by us, are not consistently affected, and the results of at least a thousand white and differential blood counts we performed, but have not reported here, do not suggest that the leucocyte pattern is altered, except for an occasional increase in the eosinophiles, during the entire course of gold therapy. Also the bacteriostasis is not maintained, as might be expected from a stimulation of the protective mechanisms, but is rapidly lost after the cessation of gold salt administration.

The evidence induced by these experiments, therefore, supports the theory that gold salts could act by a direct effect on the causative agent of the rheumatoid arthritis, assuming that the causative agent is infectious. Such a mechanism now appears to be the case after the administration of sulfanilamide and allied compounds. In what way this would take place, by coagulation of the bacterial proteins, interfering with the processes of oxidation and reduction of bacterial metabolism, or by actual dissolution of the organism, is, of course, purely hypothetical; as a matter of fact, it is equally hypothetical at present in the case of sulfanilamide and most other forms of chemotherapy.

Still another mode of action of gold salts has been suggested. In experimental tuberculosis it was considered by some investigators that gold owes its effects to a toxic action on the capillary endothelium. Hyperemia, hemorrhage, and edema have been demonstrated about the tuberculous lesions. Also gold was found to be more toxic for tuberculous animals than for the controls. Whether similar phenomena take place in rheumatoid arthritis has not been determined.

An understanding of the mode of action of gold salts is important, since it might carry with it a knowledge of the kind of patients in which gold is

likely to succeed, a rational system of dosage, an explanation of the failures, and an indication of the lines which might profitably be followed in the development of new compounds. It is well known in chemotherapy that the slightest modification of a molecule carries with it profound changes in curative or toxic properties. This has been especially demonstrated in the past in the development of the pentavalent arsenic series.

Also the intermediate and final fate of gold salts injected parenterally must be thoroughly investigated. However, until an adequate method for the quantitative determination of gold salts and their derivatives in the blood, organs, and excreta, is at hand, knowledge concerning their absorption, distribution, and excretion will be lacking, and a rational system for administration cannot be developed. This latter knowledge is of special importance, in view of the toxic effects so commonly sequential to gold therapy.

CONCLUSIONS

1. Subcutaneous injections of gold sodium thiomalate administered to rheumatoid arthritis patients in divided doses totaling as little as 60 mg. and up to 921 mg. were followed by a marked increase in the bacteriostatic power of the serum against hemolytic streptococcus, strain Greene.

2. The observed bacteriostatic effects were in rough proportion to the total amount of gold sodium thiomalate given; the maximum effect being attained after from 147 to 155 mg. had been administered. The bacteriostasis disappeared after stopping the administration for three to six months.

3. Parenteral injections of gold sodium thiomalate did not significantly increase or decrease the agglutinin titers for hemolytic streptococcus, strain Greene.

4. Colloidal gold in amounts administered by us did not produce significant bacteriostasis. Bismuth subsalicylate was hardly more effective.

5. Gold sodium thiomalate was found to be bacteriocidal in vitro against streptococcus hemolytic strain Greene, in dilutions through 0.000001 per cent, and bacteriostatic in higher dilutions. Other common laboratory organisms were similarly, though not as markedly, affected. The in vitro bacteriostasis was roughly proportional to the concentration of gold salt. The addition of whole blood to the extent of 50 per cent of the final dilutions in these in vitro studies almost completely destroyed the bacteriostatic effect.

580 PARK AVENUE

TREATMENT OF PNEUMONIA IN RATS*

A COMPARATIVE STUDY OF THE THERAPEUTIC EFFICIENCY OF SULFAPYRIDINE AND RABBIT SERUM, AND COMBINATIONS OF THE TWO, IN ARTIFICIALLY INDUCED TYPE I PNEUMOCOCCUS INFECTION OF ALBINO RATS

SAMUEL H. SPITZ, M.D., ELMER H. LOUGHLIN, M.D., AND
RICHARD H. BENNETT, M.D., BROOKLYN, N. Y.

GROSS and Cooper¹ in 1937 treated type I pneumococcal infections in rats with sulfanilamide and rabbit antipneumococcus serum, alone and in combination. They concluded, from their experiments, that sulfanilamide was better than serum and that combined therapy was more effective than either therapy alone.

In 1939, Kepl and Gunn² similarly treated type I pneumococcal infections in rats with sulfapyridine and rabbit serum. They concluded that, when treatment was begun within four hours after inoculation, the combined use of serum and sulfapyridine was more effective than either alone. But, when infection was well established, serum was more efficacious than sulfapyridine; while at this stage the combined use of these preparations offered no more than serum alone.

Both groups of workers inoculated the animals intrabronchially with type I pneumococci suspended in gastric mucin. Neither, however, report on blood cultures prior to and during treatment of the animals, making it difficult, therefore, to evaluate accurately the effectiveness of any therapy used, since the presence of infection had not been definitely established.

*From the Department of Internal Medicine, Long Island College of Medicine.

This work was made possible by a Fellowship Grant from the Lilly Research Laboratories, Indianapolis, Ind., and by the Dr. Frank E. West Fund, established by Miss Elizabeth Frothingham, and the John C. Warren Memorial Fund, established by Dr. Luther F. Warren, in memory of his son.

Received for publication, April 22, 1940.

The experiments we report here were done to determine the comparative effectiveness of sulfapyridine and type I rabbit antipneumococcus serum when used alone and in combination in the treatment of type I pneumococcal infection in rats.

FIG. 1.

METHODS

Inoculation of the rats, as described in a previous paper,³ was done by spraying a pneumococcal culture into both the pharynx and nares. This culture, which was suspended in 15 c.c. of a physiologic solution of sodium chloride, consisted of the washings of the peritoneal cavity of a white mouse infected with type I pneumococci (RI strain), and contained, as a result of the peritoneal inflammation, natural mucin in addition to the other components of an inflammatory exudate. The procedure was entirely nontraumatizing.

To insure accurate dosage, the sulfapyridine was suspended in diluted condensed milk and was introduced through a stomach tube. The serum was administered by intraperitoneal injection.

A total of 67 rats, weighing approximately 300 Gm. each, were thus inoculated. Fifty-six became infected, as manifested by the development of positive blood cultures. Cultures of the blood were made prior to treatment, at six hours and twenty-four hours after inoculation, and were repeated at twenty-four-hour intervals, until spontaneous death occurred or recovery ensued. Only those animals of the control and treated series which developed blood stream invasion were included in this report.

The 56 rats which became infected were separated into two series, each of which, in turn, was divided into four groups.

In Series I, consisting of 22 rats, treatment was started six hours after inoculation, and blood for culture was taken just prior to beginning treatment. Included in this series were: Group A, 6 untreated controls. Group B, 5 animals which were treated with seven doses each of 150 mg. of sulfapyridine at twenty-four-hour intervals. Group C, 5 animals which were treated with three doses each of 400 units of type I rabbit antipneumococcus serum at twenty-four-hour intervals. Group D, 6 animals which were treated with three doses each of 200 units of type I antipneumococcus serum at twenty-four-hour intervals and seven doses each of 75 mg. of sulfapyridine at twenty-four-hour intervals.

In Series II, consisting of 34 rats, treatment was started twenty-four hours after inoculation. Blood cultures were made prior to institution of treatment at six and twenty-four hours after inoculation. Included in this series were: Group E, 8 untreated controls. Group F, 8 animals which were treated with three doses each of 225 mg. of sulfapyridine, at intervals of twenty-four hours. Group G, 9 animals which were treated with three doses each of 600 units of type I antipneumococcus serum at twenty-four-hour intervals. Group H, 9 animals which were treated with three doses each of 300 units of type I antipneumococcus serum at twenty-four-hour intervals and seven doses each of 150 mg. of sulfapyridine at twenty-four-hour intervals.

RESULTS

Series I (Treatment begun at six hours). Group A: All 6 untreated controls died, the mortality rate being 100 per cent. The average period of survival was three days. Group B (Sulfapyridine): Three of the 5 rats died the mortality rate being 60 per cent. The average period of survival of those dying spontaneously was 7.6 days. Group C (Serum): All five rats recovered the mortality rate was zero per cent. Group D (Sulfapyridine and serum): One of the 6 rats died on the seventh day; the mortality rate was 16.6 per cent.

Series II (Treatment begun at twenty-four hours). Group E: Seven of the 7 untreated controls died spontaneously, the mortality rate being 86 per cent. The average period of survival was three days. Group F (Sulfapyridine): Five of the 8 rats died; the mortality rate was 62.5 per cent. The average survival period of those dying spontaneously was 5.6 days. Group G (Serum): Two of the 9 rats died, the mortality rate being 22.2 per cent. The average period of survival of those dying spontaneously was five days. Group H (Sulfapyridine and serum): Two of the 9 rats died; the mortality rate was 22.2 per cent. The average survival period of those dying spontaneously was 4.5 days.

In the animals that recovered, the blood cultures, on the average, became negative on the fourth day of sulfapyridine therapy, on the third day of serum therapy, and on the fourth day of serum and sulfapyridine therapy.

Post-mortem Results.—All rats which survived were killed at the end of the fourteenth day and autopsied. The results of the post-mortem examination confirmed the existence of previous infection.

Of the 26 rats that died spontaneously, in both the control and treated groups, it was found that 6 (A1, E2, E7, F1, F4, and F5) had pneumonia and

SERIES II - SURVIVAL PERIOD OF RATS FIRST TREATED AT 24 HOURS

Fig. 2.

% OF SURVIVALS AND MORTALITY RATES OF RATS INFECTED WITH TYPE I PNEUMOCOCCI

Fig. 3.

empyema; 5 (A2, A4, E3, E6, and H2) had pneumonia, empyema, and pericarditis; 3 (A6, B2, and D1) had pneumonia and pericarditis; 2 (E1, F3) had pneumonia alone; 2 (G1, G2) had pneumonia, pericarditis, and meningitis; 2 (A3, E4) had pneumonia, pericarditis, and peritonitis; 2 (B1, F1) had bilateral empyema; 1 (A5) had pericarditis alone; 1 (B3) had meningitis alone; 1 (E5) had meningitis, empyema, and peritonitis; and 1 (H1) presented no lesions.

SUMMARY AND CONCLUSIONS

1. Type I pneumococcal infection, as manifested by positive blood cultures, was produced in 56 albino rats. Sulfapyridine alone, type I rabbit antipneumococcus serum alone, or sulfapyridine and serum in combination, were administered to 42 animals, treatment having been started at either six hours or twenty-four hours after inoculation.

2. In the treatment of pneumonia in rats, type-specific serum appeared to be more efficacious than sulfapyridine alone; whereas a combination of serum and sulfapyridine in approximately one-half the dosage of either used separately gave no better results than serum without sulfapyridine.

We wish to express our appreciation to Doctors Tasker Howard, J. Hamilton Crawford, Wade W. Oliver, and Arnold Eggerth for their aid and criticism in the preparation of this paper, and to Misses Anne Smith and Dora Zuckerman for their aid in the preparation of the bacteriologic material used.

CHROMOPHOBE PITUITARY ADENOMA WITH SIMMONDS' DISEASE*

CASE REPORT WITH AUTOPSY

THOMAS J. MORAN, M.D., MAYVIEW, PA., AND GEORGE H. FETTERMAN, M.D.
PITTSBURGH, PA.

ANTERIOR pituitary tumors causing a clinical and pathologic pattern resembling Simmonds' disease (pituitary cachexia) are of sufficient rarity to justify the report of a single case.

The present report deals with the post-mortem finding of a large cystic chromophobe adenoma of the anterior pituitary body in a middle-aged negress, and serves to explain a train of mental, visual, and cachectic disturbances noted clinically.

The knowledge regarding Simmonds' disease has increased considerably since Simmonds¹ first report in 1914. A helpful summary of the outstanding pathologic and clinical characteristics of the condition, as accepted today, was given in 1938 by Farquharson, Belt, and Duff² who also reported one of the largest personal series of cases.

Excellent reviews of the literature were made by Calder in 1932³ and Silver in 1933.⁴ Of the 70 cases from the world's literature collected by Calder and accepted by him as true examples of Simmonds' disease, only 9 were due to tumors or cysts. Several other writers have mentioned the rarity of cases of Simmonds' disease due to neoplasm, although Horrax,⁵ in speaking of material encountered in a neurosurgical clinic, stated that "cases of tumor exhibiting evidences of Simmonds' disease . . . are not particularly infrequent."

REPORT OF CASE

History.—M. G., aged 54 years, a widowed negress and a domestic by occupation, was admitted to the Mental Department of the Pittsburgh City Home and Hospitals on July 9, 1936. Her complaints at this time were sleepiness, nervousness, weakness, lack of energy and interest, and inability to work.

Married and widowed, she had had one pregnancy that resulted in miscarriage. In 1922 her uterus and adnexa had been removed for fibromyomas, chronic salpingitis, and ovarian cysts. Her normal weight was 118 pounds.

She had been employed and in good health until the spring of 1934, when she began to notice abnormal sleepiness. Sometimes she would sleep continuously for as long as sixteen or seventeen hours. She also noticed pain in her back, hips, and legs.

During the following year she had several "spells," in which everything "went black." During these attacks she stated that she lost consciousness, but had no convulsions and no urinary incontinence.

*From the Department of Pathology of the Pittsburgh City Home and Hospitals, Mayview, Pa., and The John C. Oliver Memorial Research Foundation, St. Margaret Hospital, Pittsburgh, Pa.

Received for publication, April 23, 1940.

In March, 1936, she visited the outpatients clinic of a Pittsburgh hospital with the above complaint. Her physical examination was reported negative at this time. Blood pressure was 100/70. Urinalysis was negative. Blood Wassermann and Kahn tests were negative. Blood sugar was 100 mg. Blood urea was 16.6 mg., fasting blood sugar was 84 mg. per 100 cc. She made no further visits to this clinic.

Between this time and her present admission she complained of seeing "bugs on blankets" and "pygmies in corners," both of which were apparently visual hallucinations.

Because of her queer behavior her sister summoned a city physician in July, 1936. This physician recommended her admission to a mental hospital. He noted "low blood pressure, general asthenic symptoms of neurasthenia bordering on melancholia, and unwillingness to eat."

During her twenty-day stay in the observation ward, the patient was listless and quiet. She was cooperative, but often nervous and depressed. She was always sleepy. During an interview she fell asleep in her chair several times. She complained of numbness and weakness in her arms and legs, and lack of appetite. She stated that she had been eating only one meal daily while at home. She remembered the visual hallucinations but experienced them no more. Her general knowledge was poor. She was coherent and relevant in her answers. Her emotional reaction was simple and childish. Her orientation was correct and her memory was good. She was not delirious.

The family history was irrelevant except that one sister had died of a mental disease of unknown classification.

Physical Examination.—The patient was a well-developed mulatto negress, weighing 101 pounds. The upper jaw was edentulous; the lower teeth were carious. The pupils reacted sluggishly to light. The chest was clear. The blood pressure was 120/64. Pulse rate was 82 per minute. The temperature was 99.6° F. The abdomen was soft, with wrinkling of the skin. There was an old midline abdominal scar. Reflexes were noted as normal at this time. No other significant findings were recorded. Blood Hinton, Kahn, and Wassermann tests were negative. Urinalysis was negative.

Progress.—The patient was brought before the committing staff on the tenth day of hospitalization. She was not committed but was transferred to the Home Department, with a diagnosis of mental deficiency and dental caries.

In the Home Department she attracted little notice. She lost weight gradually, failed in strength, and had increased difficulty in swallowing. She was apathetic and mentally dull. Her sight failed gradually. She helped with the work around the ward until prevented by her increasing weakness. She became bedridden and helpless in September, 1937. On October 10, 1937, she had an epileptiform convulsion. From this point on she failed rapidly. She was almost blind in November. On November 9, 1937, she passed into a semicomatose state from which she never recovered. On December 2, 1937, she had three epileptiform seizures. On December 7, 1937, she died.

Clinical Diagnosis.—Cachexia of unknown origin.

Autopsy.—Autopsy was performed three hours after death.

The body was extremely emaciated, weighing only 75 pounds. The scalp hair was of normal amount, black, and kinky. The skin of face was loose and wrinkled, as was the skin of the abdomen. The breasts were flat and atrophic. The abdomen presented many old white striae. There was an old healed 15 cm. midline scar below the umbilicus. Pubic and axillary hair were scanty. The escutcheon was feminine. There were many dependent pressure sores, including ones in the scapular, trochanteric, and sacral regions. There were also sores over either external malleolus. There was dependent edema of both lower legs.

The pupils were round, regular, and equal, each measuring 0.4 cm. in diameter. The upper jaw was edentulous; the teeth remaining in the lower jaw were carious. The lower jaw was prominent, long, and protruding. The chest was flat and symmetrical. The abdomen was soft and flat.

Head.—On attempting to remove the brain, a large partially cystic tumor mass was discovered in the sella turcica, extending up into the base of the brain. The brain was removed without rupture of the cystic portions of the tumor. The solid portion of the tumor

FIG. 1.—Showing tumor at base of brain. The cystic lobes are seen on either side

FIG. 2.—Sagittal section of the cerebrum showing the solid portion of the tumor pressing against the fornix and corpus callosum.

had to be removed forcibly from the right side of the sella. At this point part of the mushy, gelatinous tumor substance was left behind, where it had eroded through the pituitary capsule and adjacent dura, and grown around the right internal carotid artery in the cavernous sinus. The floor of the sella was thinned, but its continuity was unbroken. The sella was 2.25 cm. long, 2.50 cm. wide, and 2 cm. deep. Except for the sellar enlargement, the base of the skull was not remarkable.

Brain.—The brain weighed 1,400 Gm. and measured 17.75 by 14 by 9.5 cm. The tumor mass at the base of the brain was 10 cm. wide, 6 cm. long, and 6.5 cm. in depth (see Fig. 1). The tumor was composed of a solid sellar portion and two symmetrical cystic prolongations, one extending into either cerebral hemisphere.

The solid sellar portion presented a flat, yellowish-gray, soft but firm, granular, and friable cut surface.

The cystic prolongations were remarkable in their symmetry, large size, and encroachment upon frontal and temporal lobes. Each of these two cystic units measured 5 by 4.75 by 4.50 cm. Sagittal section of the cerebrum passed through the septum, dividing the two cysts so that neither was ruptured by the cut. The cyst walls were thin and fragile, with a dull bluish translucence. Each was filled with brown finely flocculent fluid. The extension of the cysts into brain substance was anterolateral in either case. On the left side the bluish translucency of the cyst could be seen externally in the divulged lateral fissure in the frontal lobe.

No actual invasion of the brain tissue was observed, but there was compression atrophy of both frontal and temporal lobes, with flattening of the convolutions and near obliteration of the sulci over the vertex.

The arterial and nervous elements at the base of the brain were greatly distorted. The basilar artery and the vertebral arteries were thin and attenuated. The divisional branches of the basilar artery gave off thin communicating branches to the internal carotid arteries on either side of the tumor. The anterior cerebral arteries could not be identified. The optic nerves were stretched, thinned, and flattened. The cystic prolongations reached anteriorly to the tip of either frontal lobe and extended back along the corpus callosum to the plane of the mammillary bodies (Fig. 2). The solid portion of the tumor extended from the sella up to the fornix where it had caused thinning of the fornix and corpus callosum. The solid tumor nearest the fornix was necrotic, being reddish-brown, mushy, and granular.

Microscopic Description.—From formalin-fixed tissue paraffin sections were made and stained with hematoxylin and eosin, phosphotungstic acid-hematoxylin, van Gieson's connective tissue method, Wilder's reticulum stain, and Spark's differential stain for pituitary cells.

The tumor was predominantly chromophobic. Small, slightly elongated or polyhedral cells were arranged usually in compact solid sheets and cords (Fig. 3), but often grouped around tiny blood vessels to form pseudorosettes (Fig. 4). A scanty, irregular fibrous connective tissue stroma was present. The essential cells were of two types (Fig. 5). The commoner type was large and vesicular, with a heavy chromatin network and moderate variation in size and shape. The other type was smaller, with a compact, almost solidly staining chromatin content. There were very occasional normal mitotic figures. The cytoplasm of most cells was scanty, pale, slightly granular, and neutrophilic. In the phosphotungstic acid-hematoxylin stains numerous, fine, rodlike mitochondria were found distributed chiefly in the periphery of the cytoplasm. In one small area a few large eosinophilic cells were seen. Near these eosinophilic remnants was a tiny microscopic colloid cyst, similar to the cysts found in the normal pars intermedia.

The cyst walls were composed of fibrous tissue in whose meshes were many columns of tumor cells, similar to those in solid portions of the growth. Smear of the cyst fluid showed numerous red blood cells and an occasional tumor cell.

Neck.—Unfortunately the thyroid gland was not examined.

Thorax.—The left lung weighed 160 Gm., the right lung 270 Gm. The heart was very small, weighing only 135 Gm.

Abdomen.—The liver weighed 750 Gm., the spleen 50 Gm. The left kidney weighed 165 Gm., the right kidney 110 Gm. The adrenals were small and generally atrophic.

Fig. 3.—Photomicrograph of tumor (X368) showing typical arrangement of chromophobe cells; a scanty fibrous tissue stroma is seen (H. & E.).

Fig. 4.—Photomicrograph of tumor (X368) showing perithelial rosettes (H. & E.).

Fig. 5.—Photomicrograph of tumor (X736) showing two types of chromophobe nuclei (H. & E.).

Microscopic examination of thoracic and abdominal organs revealed nothing of interest.

Pathological Diagnoses.—Cystic chromophobe adenoma of pituitary body, Simmonds' disease, emaciation, microsplanchnia.

COMMENT

Although certain phases of the clinical study in this case are incomplete, the entire picture conforms with that of Simmonds' disease.

Admittedly many of the clinical findings might be explained on the basis of an enlarging intracranial tumor in the region of the optic chiasm with pressure on neighboring structures. Nevertheless, the clinical presence of anorexia, progressive emaciation, mental impairment, asthenia, and somnolence, combined with the post-mortem findings of pituitary destruction and microsplanchnia, justify, in our opinion, the inclusion of this case in the Simmonds' group.

The neurologic symptoms are interesting, and could be due either to "neighborhood signs" of a tumor or to anterior pituitary destruction.

From a morphologic standpoint the tumor is benign. The fact that the tumor extended into the cavernous sinus is not in contradiction to this belief. There was compression of brain substance at other points but never replacement.

The finding of pituitary tumor and Simmonds' disease in a patient in a mental and home department re-emphasizes the well-known fact that a large percentage of organic pituitary disorders are to be found in such institutions.

CONCLUSIONS

1. A case of Simmonds' disease with pituitary tumor is reported with autopsy findings.

2. The tumor, a semicystic chromophobe adenoma, had resulted in complete destruction of the pituitary body.

THE HISTOPATHOLOGIC CHANGES IN MYELINATED NERVE FIBERS OBSERVED BY THE POLARIZED LIGHT METHOD FOLLOWING ARTIFICIALLY INDUCED HYPERPYREXIA*

H. M. WEAVER, DETROIT, MICH.

INTRODUCTION

THE introduction of artificially induced hyperpyrexia as a modern clinical practice has aroused in the minds of many investigators the desire to know the possible histopathologic effects of varying lengths of exposure to carefully controlled body temperatures. In cooperation with the Departments of Medicine, Pathology, and Anatomy of The Ohio State University, an extensive survey of the effects of hyperpyrexia was undertaken. The scope of this communication will be limited to that portion of the work concerned with the possible histopathologic alterations of peripheral myelinated nerve fibers from animals subjected to artificially induced hyperpyrexia.

MATERIALS AND METHODS

Healthy, young adult rabbits of both sexes were chosen as experimental animals.

Hyperpyrexia-Producing Techniques.—Two distinctly different types of hyperpyrexia-producing machines were used in this investigation, viz., (1) the Kettering hypertherm, and (2) a radiotherm.

The Kettering hypertherm employed was the same machine that is used for the treatment of patients in the Outpatient Clinic of The Ohio State University Hospital. Elevation of the body temperature occurs in this machine (1) whenever the temperature of the enclosed air exceeds that of the body, and (2) whenever the humidity of this same air becomes sufficiently great to prevent evaporation of sweat from the surface of the body. It should be emphasized here that this method of producing hyperpyrexia does not depend primarily upon increased heat production by the body, but instead it elevates the body temperature by depressing the efficiency of the mechanisms for heat loss.

The radiotherm employed was designed and built by Professors E. E. Dreese and J. F. Byrne, of the Department of Electrical Engineering of the Ohio State University, for use in the study of experimental animals. The machine consists of a cabinet on two sides of which are located the electrode plates. Numerous apertures in the cabinet provide adequate circulation, and fiber-board guards prevent the animal from being burned by the electrodes. The machine produces wave lengths of 25 meters at 12,000,000 oscillations per second, and its radio

*From the Department of Anatomy, Ohio State University School of Medicine, Columbus, and Department of Anatomy, Wayne University College of Medicine, Detroit.
Received for publication, April 24, 1946.

frequency can be varied from 0.02 to 0.5 amperes, or 1 to 4 thermoamperes. Production of hyperpyrexia by this method, in contrast to hyperthermy, is due to heat generated in the animal's tissues by the passage of an electric current.

Parallel periods of hyperpyrexia were induced by the hypertherm and radiotherm techniques, respectively, and the tissue changes were compared. The investigation included the production of high temperatures for short lengths of time, as well as relatively low temperatures maintained over long intervals. Some of the animals were subjected to hyperpyrexia until death resulted, whereas others were allowed to recover. In a few instances rabbits were subjected to intermittent periods of sublethal hyperpyrexia over considerable intervals of time.

During each extended period of hyperpyrexia all animals were given approximately 50 c.c. of 1 per cent glucose in normal saline by stomach catheter at three-hour intervals. The quantity of fluids administered and the frequency of the dose were varied to that necessary to maintain a constant body weight.

Rectal temperatures in degrees Fahrenheit were recorded from each animal at fifteen-minute intervals during all periods of experimentally induced hyperpyrexia.

All animals not subjected to lethal temperatures were canceled by air emboli. Complete autopsies were performed immediately after death in all cases.

Histopathologic Method.—Preliminary observations demonstrated the necessity of a sensitive technique for the study of the possible alterations in the peripheral myelinated nerve fibers of the animals used in this experiment. The work of Baldi,¹ Setterfield and Sutton^{2, 3} Sutton, Setterfield, and Krauss,⁴ Setterfield and Baird,⁵ Setterfield and Weaver,⁶ Toomey and Weaver,^{7, 8} and Weaver and Kitchin⁹ has convinced me that the polarized light method is the most sensitive and accurate technique available for studying degenerative phenomena in peripheral myelinated nerve fibers.

The nerves to be studied were removed from the animal at autopsy, laid out without stretching on a segment of a tongue depressor, and fixed for twenty-four hours or longer in a solution of 10 per cent neutral-formalin. The nerves were then cut longitudinally on a freezing microtome at a thickness of 10 microns. The sections were floated onto slides from water and mounted in neutral glycerin.

Examination of peripheral myelinated nerve fibers by the polarized light method reveals the presence of two optically different materials, namely, (1) those exhibiting the phenomenon of birefringence, and (2) those characterized by the state of isotropism. In rotating the stage of the microscope through 360 degrees, the birefringent material can be seen to become alternately light and dark four times in each revolution. The isotropic material, on the other hand, remains dark at all points in the revolution of the stage.

In general, the appearance of peripheral myelinated nerve fibers, as seen in polarized light, closely resembles that revealed by the classic techniques. The axis cylinder, neurokeratin framework, and myelin sheath require special description.

The axis cylinder (Figs. 1 and 2), as commonly referred to in the literature, is composed of two portions, i.e., (1) an inner cylindrical rod, the true axis cylinder; and (2) an outer enveloping sheath, the non-neurofibrillated portion of the axis cylinder. In polarized light the true axis cylinder is isotropic, deep black, homogeneous, and of uniform caliber throughout its length. The non-neurofibrillated portion of the axis cylinder, as seen in polarized light, is isotropic, but less intensely black than the true axis cylinder, and very slightly

granular. Most authors have described the axis cylinder to be of constant caliber, except for a constriction at the level of the cementing disk, above and below which there is an enlargement. By reference to Fig. 1 it can be seen that it is the non-neurofibrillated portion of the axis cylinder only that is involved in this enlargement and in the constriction.

EXPERIMENTAL PROCEDURE, OBSERVATIONS AND RESULTS

GROUP	NO. OF ANIMALS	FEVER MACHINE	TREATMENT	MICROSCOPIC APPEARANCE OF NERVE FIBERS
A	16		Control	Normal (Figs. 1 and 2). The nerve fibers in this species of animal are somewhat peculiar in that the non-neurofibrillated portion of the axis cylinders show some slight peripheral irregularity, and are characterized by a more or less pronounced vacuolization just above and below the cementing disk. Whenever these terms are employed in the description of nerves from experimental animals, it is to be understood that they represent changes over and above that seen in a normal fiber.
B	4	Radiotherm	Lethal temperature	Normal
C	2	Hypertherm	Lethal temperature	Normal
D	2	Radiotherm	109.0° F. until death	Extensive peripheral irregularity and marked vacuolization at the nodes of Ranvier of the non-neurofibrillated portion of the axis cylinders. Numerous petechiae in the nerve trunk. In one animal degeneration was more marked in 60 per cent of the fibers. In the latter (Fig. 4) the myelin sheath contained much isotropic material; approximately 25 per cent of the true axis cylinders were fragmented; the non-neurofibrillated portions of the axis cylinders were badly swollen fragmented, and more markedly vacuolated; the neurokeratin framework was swollen and isotropic; nodes of Ranvier were hardly recognizable; and the sheath of Schwann apparently contained more nuclei than normal.
E	2	Hypertherm	109.0° F. until death	The nerve fibers showed some edema; the axis cylinders, both the true and non-neurofibrillated portions, showed an extreme degree of vacuolization and fragmentation in the majority of the fibers; the myelin sheath contained numerous globules of isotropic material; the nodes of Ranvier were scarcely recognizable, but when seen were swollen and filled with isotropic material; the neurokeratin framework was either isotropic or hidden in the adjacent degenerated debris; the sheath of Schwann was edematous (Fig. 3).
F	2	Radiotherm	108.0° F. until death. One animal canceled after 13 hours	All fibers showed peripheral irregularity of the non-neurofibrillated portion of the axis cylinders. In half the animals the neurokeratin framework was swollen and isotropic, and there was edema of the non-neurofibrillated portion of the axis cylinders. One animal showed vacuolization and fragmentation of the non-neurofibrillated portion of the axis cylinders, and fragmentation of a large proportion of the true axis cylinders, together with considerable derangement of the nodes of Ranvier. Two animals showed isotropic material in the myelin sheaths.

EXPERIMENTAL PROCEDURE, OBSERVATIONS, AND RESULTS—CONT'D

GROUP	NO. OF ANIMALS	FEVER MACHINE	TREATMENT	MICROSCOPIC APPEARANCE OF NERVE FIBERS
G	2	Hypertherm	108.0° F. until death	The myelin sheaths contained some isotropic material; the neurokeratin framework was swollen and isotropic; in about 50 per cent of the fibers the non-neurofibrillated portions of the axis cylinders showed peripheral irregularity and were markedly vacuolated, and some showed considerable edema.
H	2	Radiotherm	107.0° F. until death	Normal
I	2	Hypertherm	107.0° F. until death	The non-neurofibrillated portion of the axis cylinders showed some edema, peripheral irregularity, and marked vacuolization. In one animal the neurokeratin framework was isotropic and swollen slightly, and one petechia was observed.
J	1	Hypertherm	103.5° F. for 43½ hours and canceled	The neurokeratin framework was slightly swollen and 10 per cent of the fibers showed edema of the non-neurofibrillated portion of the axis cylinders.
K	2	Radiotherm	Intermittent periods of 106.5° F. Total of 18 hours. Seven days recovery	In one animal there was a slight swelling, peripheral irregularity, and vacuolization of the non-neurofibrillated portion of 15 per cent of the axis cylinders. In the other animal these changes were more marked, especially at the nodes of Ranvier. Ten per cent of the fibers in this animal showed fragmentation of the true axis cylinders and isotropic material in the myelin sheaths.
L	2	Hypertherm	Intermittent periods of 106.5° F. Total of 18 hours. Seven days recovery	One animal showed slight vacuolization of the non-neurofibrillated portion of the axis cylinders. In the other animal the fibers were normal, except for those in one small fasciculus which were characterized by a marked vacuolization of the non-neurofibrillated portion of the axis cylinders.
M	2	Hypertherm	Intermittent periods of 108.0° F. Total of 50 hours. Seven days recovery	One animal showed peripheral irregularity of the non-neurofibrillated portion of the axis cylinders and marked vacuolization in 10 per cent of these structures. In the other animal the non-neurofibrillated portion of the axis cylinders was slightly vacuolated, and the neurokeratin framework was slightly swollen and isotropic.
N	2	Radiotherm	108.0° F. for 8 hours. Thirty days recovery	In one animal the nerves were normal. In the other animal the fibers showed a marked vacuolization of the entire length of about 10 per cent of the non-neurofibrillated portions of the axis cylinders, and some isotropic material in the myelin sheaths.
O	2	Hypertherm	108.0° F. for 8 hours. Thirty days recovery	The myelin sheaths contained numerous globules of isotropic material; the neurokeratin framework was swollen and isotropic; there was peripheral irregularity of the non-neurofibrillated portion of the axis cylinders in 50 per cent of the fibers, and marked vacuolization of the entire length of these structures in about 25 per cent of the fibers. In one animal there was considerable derangement of the nodes of Ranvier.

In a normal nerve fiber the neurokeratin framework (Fig. 1) is very difficult to see because its index of refraction is only slightly different from that of the myelin sheath. Under an oil-immersion objective the neurokeratin framework appears as a thin, isotropic, skeletal system of anastomosing trabeculae, which bridge across the myelin sheath from the non-neurofibrillated portion of the axis cylinder to the sheath of Schwann. This spongy neurokeratin framework contains potential cavities of varying size—potential because they are filled with true myelin. In certain edematous and degenerative changes of the nerve fiber the neurokeratin trabeculae become larger and somewhat darker.

Fig. 2.—Rabbit 100, Group A. $\times 1,575$ diameters.

The myelin "sheath" (Fig. 1) is, in polarized light, the only structure in the nerve fiber exhibiting the phenomenon of birefringence. Under high magnification it becomes apparent that the myelin is not in the form of a sheath, but instead is present as variously-shaped globules confined to the interstices of the neurokeratin framework. As degenerative changes in a nerve fiber progress, the myelin progressively loses its birefringency and becomes isotropic.

DISCUSSION

An examination of the histopathologic changes noted in the peripheral nerves of the animals presented in this study reveals the necessity of a declaration of their reversibility or irreversibility.

During earlier studies on poliomyelitis (Toomey and Weaver⁷) it was pointed out that fragmentation of the true axis cylinders was always associated with some degree of muscular dysfunction. During acute stages of polio-

Fig. 3.—Rabbit 146, Group E. $\times 1,575$ diameters.

Fig. 4.—Rabbit 150, Group D. $\times 1,575$ diameters.

myelitis the number of true axis cylinders showing fragmentation were noted. If animals under similar conditions were allowed sufficient time to recover and their nerves again examined, the number of nerve fibers showing complete degeneration corresponded closely to the number of nerve fibers showing fragmentation of the true axis cylinders during the acute stages of the disease. From this observation it was inferred that fragmentation of the true axis cylinder is irreversible in character, though it must be kept in mind that regeneration of the fiber may occur if the cell body is not destroyed.

Peripheral irregularity, vacuolization, and fragmentation of the non-neurofibrillated portion of the axis cylinder may be considered reversible in character, although these changes are indicative of injury to the nerve fiber. The intensity of the injury probably becomes progressively greater in the order that they have been named. The truth of this statement is indicated by the fact that in acute stages of poliomyelitis almost every nerve fiber is affected by these changes. If an animal showing these changes (for example, an animal suffering from acute poliomyelitis but showing little muscular dysfunction) is allowed sufficient time to recover and their nerves are again examined, essentially all the nerve fibers will appear normal.

It should be pointed out that some vacuolization, especially at the nodes of Ranvier, and some peripheral irregularity throughout its entire length, is characteristic of the non-neurofibrillated portion of the axis cylinders of fibers from a normal animal. Whenever these terms were employed in the description of the nerves from the experimental animals employed in this investigation, it is to be understood that they represent a change over and above that seen in a normal fiber.

The presence of isotropic granules in the myelin sheaths is undoubtedly an example of an irreversible type of degenerative change, although the presence of these granules is not necessarily indicative of neurologic dysfunction. From a series of isolated observations on the nerves of animals subjected to varying types of stress, during both acute and recovery stages, it is believed that these isotropic granules are removed by the phagocytic activity of the neurilemma cells.

Edema of the fiber as a whole, or of any of its parts, with the single possible exception of the true axis cylinder; irregularity and waviness of the fiber; and swelling with increased isotropism of the neurokeratin framework, are all considered to be reversible in character, and, when present alone, to be indicative of rather mild injury to the nerve fiber.

Although it was in most cases considerably more difficult to maintain a constant temperature by radiothermy than by hyperthermy, a cursory examination of the descriptions of the peripheral nerves reveals that degenerative changes were more marked in the series subjected to radiothermy. There appear to be only two possible explanations for this seeming dissimilarity: (1) The difference in the microscopic picture of the nerves of the animals in the two series subjected to practically identical periods of average temperature may, in some cases at least, be explained by the fact that animals in the radiothermy group were allowed to move about freely, whereas the production of hyperpyrexia by hyperthermy necessitated restraining the animals so that their heads could be

retained outside the machine. Examination of the gross necropsy findings in the animals in both the radiotherapy and hyperthermy groups revealed a marked derangement of the blood vascular system. Since the efficiency of peripheral circulation is influenced greatly by the tone and activity of limb muscles, it is only logical to assume that restraining the animal from moving would tend to depress the efficiency of the already nearly (or actually) inadequate circulatory system and, thereby, tend to hasten anoxia in the extremities. Since it is well known that nervous tissue as a whole is particularly sensitive to this condition, it might be utilized as an explanation, in part at least, for the more pronounced picture of degeneration in the nerves of the hyperthermy animals. (2) The passage of short radio waves through the tissues of the animal may in some manner unknown to me serve to counteract the deleterious effects of hyperpyrexia or of its sequelae.

Experiments are now in progress in which anoxia has been produced without elevation of the body temperature. Comparison of the tissues of these animals with those just described will, we trust, enable us to make a more definite statement as to the etiology of the histopathologic changes following artificially induced hyperpyrexia by the methods of radiotherapy and hyperthermy.

The description of the histopathologic changes noted in the peripheral nerves of the different groups of animals reported in this paper has been summarized. No further discussion is indicated.

SUMMARY AND CONCLUSIONS

In cooperation with the Departments of Medicine, Pathology, and Anatomy of The Ohio State University, an extensive program was undertaken, the primary object of which was to determine the possible histopathologic effects of artificially induced hyperpyrexia by the methods of hyperthermy and radiotherapy. The present paper has been confined to the changes observed in the peripheral myelinated nerves of the animals used in this joint investigation.

Using rabbits as the experimental animal, the investigation extended from the production of high temperatures for short lengths of time to relatively low temperatures over long intervals. Some of the animals were subjected to hyperpyrexia until death resulted, whereas others were allowed to recover. Finally, a few rabbits were subjected to intermittent periods of hyperpyrexia over considerable intervals of time.

From examination of the peripheral nerves by the polarized light method I have reached following conclusions:

1. Degenerative changes were more marked in the series subjected to hyperpyrexia by hyperthermy than in the series subjected to comparable degrees by radiotherapy. A possible reason for this was discussed.
2. There was no change from the normal in the nerves of rabbits subjected to hyperpyrexia by hyperthermy or radiotherapy, when the duration of hyperpyrexia fell between thirty-three and seventy-five minutes, and the terminal temperatures varied from 111.5° F. to 111.9° F.
3. Hyperpyrexia by either method, in which the temperature varied between 108.7° F. and 109.1° F. , and the duration of hyperpyrexia varied from four

hours and five minutes to seven hours and two minutes, resulted in marked degenerative changes of irreversible and reversible types in the peripheral nerves of rabbits.

4. In rabbits subjected to hyperpyrexia by radiotherapy or hyperthermy until death, and in which the temperature did not exceed 108.3° F., the peripheral nerves were characterized by degenerative changes of the reversible type and, furthermore, the intensity of these changes was directly proportional to the height of the temperature. It is quite possible that changes of this nature are responsible for the occasional cases of neuritis seen in patients following artificial fever therapy.

5. In rabbits subjected to intermittent periods of hyperpyrexia (approximately one exposure of from three to six hours' duration each week, and varying from 106.1° F. to 107.84° F.)—duration of hyperpyrexia extending from eighteen to fifty hours, with one week recovery time allowed between last exposure and time of cancellation, the peripheral nerves showed only mild intensities of the reversible types of degeneration.

6. In rabbits subjected to hyperpyrexia by hyperthermy or radiotherapy in which the temperature varied between 107.65° F. and 108.05° F. for eight hours, and in which thirty days intervened between the time of exposure and the time of cancellation, the peripheral nerves showed less change in the radiotherapy group than in the hyperthermy group. In both groups, however, there was evidence of a rapid return to the normal.

I wish to express my sincere appreciation to Dr. Linden F. Edwards, associate professor of anatomy, Ohio State University, for his critical reading of and help in arranging this report; to Dr. Julien M. Goodman, then a medical student, and to Dr. Milton Berman, then a dental student, for the many hours they so patiently and skillfully devoted to the experimental procedure involved in this investigation; to Dr. Charles A. Doan, professor of medicine, Ohio State University, for his help in arranging the details of the experimental procedure of this investigation, for furnishing the experimental rabbits, and for his generosity which made available the facilities and equipment of his department; to Dr. Paul C. Kitchin, associate professor of Dentistry, for his permission to use the polarized light microscope and the photographic equipment of the College of Dentistry; and to Mrs. Elizabeth Arrowsmith for her faithful execution of the drawing presented in this paper.

CLINICAL CHEMISTRY

EFFECT ON THE NEWBORN OF VITAMIN K ADMINISTERED TO MOTHERS IN LABOR*

J. W. MULL, PH.D., A. H. BILL, M.D., AND HELEN SKOWRONSKA, M.S.
CLEVELAND, OHIO

IN AN effort to eliminate hemorrhagic disease of the newborn, we have given synthetic vitamin K, in gelatin capsules containing 1 mg. of 2-methyl-1,4-naphthoquinone in corn oil,[†] to a series of 100 women in labor. The prothrombin clotting time was then determined on the babies, starting the first or second day of life, and usually repeated every other day until at least four determinations had been made. In some few cases babies were taken on successive days, when checks seemed desirable, and others on occasion skipped two days. Each determination reported was the result of three or more successive readings. A similar study was made on a series of 100 controls.

For such a study a method economical in blood was necessary. An adaptation of the bedside method of Quick,¹ which gives a practical measure of the tendency to bleed, proved satisfactory. A total of 20 c.mm. of blood, drawn from a heel puncture, was discharged directly from the pipette into a similar amount of thromboplastin on a depression slide, and the mixture was stirred with a needle. The needle was then drawn through the blood until a clot was demonstrated. The interval between the contact of the blood with the thromboplastin and the first clot, read on a stop watch, is the prothrombin clotting time. Free flowing blood was necessary, the puncture being wiped clean each time before filling the pipette. Squeezing or milking tended to alter the results, and repeated tests from the same puncture tended to give faster clotting times. Duplicates could usually be obtained agreeing to within 0.5 second. When they did not agree, there was generally a recognizable reason, in which case the value obtained under the more satisfactory conditions was accepted.

The thromboplastin was prepared from rabbit brain as described by Quick,² and the dried product, well stoppered, was kept satisfactorily in the refrigerator. We found it advisable, however, to prepare fresh saline suspensions every third day, as with the frequent use necessary, we found a tendency toward slower results after the fourth day. The suspension was prepared by adding 0.3 Gm. of the dehydrated rabbit brain to 5 c.c. of normal saline containing 0.1 c.c. sodium oxalate (1.34 Gm. per 100 c.c.) and incubating for fifteen minutes in a water bath at 50° C. The stoppered suspension was then centrifuged very slowly for three minutes, and the milky liquid was decanted off for use. This was kept tightly stoppered in the refrigerator when not in use.

*From the Laboratory of the Maternity Hospital and the Department of Obstetrics, School of Medicine, Western Reserve University, Cleveland.

[†]Thyloquinone or Microcaps were supplied by E. R. Squibb & Sons, New York.

Received for publication, January 10, 1941.

We did not find the device of using the clotting time of a normal adult as a standard satisfactory for determining the percentage of prothrombin in the sample under investigation.³ Repeated tests on normal adults, using the same procedure with finger blood substituted for the heel puncture, showed a considerable variation from time to time. In one person, H.S., tested on 14 different occasions, there was an extreme variation of from 14 seconds to 23.7 seconds. Another, J. M., varied from 15.5 seconds to 24.2 seconds, and a third, V. M., from 16.8 seconds to 24.2 seconds. Furthermore, there is a difference between different individuals taken at the same time under the same conditions. On March 2, 1940, this amounted to almost four seconds between four normal adults; on November 26, 1940, to 1.6 seconds between two adults; and on December 19, 1940, to almost one second between two others. For this reason, we consider it better to use the average time, 19.2 seconds, determined from 21 different individual adults, as shown in Table I. We also feel it more accurate to report all findings directly in time, rather than converting them by formulas to percentages of prothrombin.

Average time for all patients			19.2

A summary of our results is presented in Table II. It is evident that the series receiving the vitamin K shows a much more rapid clotting time than the controls. The averages for each of the ten days studied is faster, the maximum values are lower in every group, and even the minimum findings are lower than those of the controls until the ninth and tenth days, by which time all infants are supposed to have re-established normal clotting times.⁴⁻⁶ More striking yet, however, is the fact that on the first and second days of life nearly a third of all the controls done were higher than the maximum found in the experimental series for those same days. On the third and fourth days over half of the controls were over the vitamin K series maximum, and even as late as

the sixth day a third showed a slower clotting time than the slowest treated patient. After the seventh day recovery is apparent, since both series approach the normal adult time. It is worthy of note that the maximum figures given in the table are not successive determinations on one or two babies, but in the ten days, are from 7 different persons.

We tried to give the vitamin K capsules with water during the first stage of labor from four to ten hours before delivery, and before any anesthesia. Naturally this was not always possible, and in 11 persons, where it was evident that the time would be longer, a second capsule was given. In 18 other women delivery followed in less than four hours. Of these, 2 showed about the average clotting time, 9 were faster than the average, and 7 were slower; none of the 7, however, was as slow as the average for the control series. There were also 18 patients who were not given a second capsule, although delivery came after ten hours. Of these, 8 were slower than the average for the treated series, 4 were faster, 5 were above average for the first day or two of life, then fell below the average, and one started slow then became better than average. One of these, below average throughout, by the fifth day had fallen below the untreated average. From this we conclude that normally absorption of the drug is fairly rapid, four hours apparently being more than ample, but that the maximum effect begins to fade after about ten hours. The 5 babies that started faster than normal only to fall below later would indicate they had more of a supply of the vitamin in their systems at birth than untreated babies, but not enough to last until they had established their own supply.

One case in the treated series stood out as a marked exception to all the rest. This mother was given two capsules, the first eleven hours forty-five minutes and the second four hours before delivery. Delivery was by breech extraction, with a large but normal baby. The five prothrombin clotting time determinations are given in Table II, but because they are so markedly different from the entire series they are not included in the averages or maximum values. Even so this one exception does not approach the higher figures of the untreated cases, as there were 9 untreated babies higher on the second day, 2 on the third, and 2 on the sixth. We have no explanation for this peculiar case, but suppose it must have been due to failure of the mother to absorb the vitamin. No jaundice was apparent in either mother or baby, and no determinations were made on the mother.

No clinical signs of bleeding were observed in either series. A few jaundiced babies were noted, usually about the fourth or fifth day, but these invariably had rapid prothrombin times, treated or untreated. None of the babies were exposed to any strain on their systems, and it may well be that, as suggested by Quick,⁷ they were delicately balanced, and clinical bleeding would have followed any disturbing factor.

We have observed a few cases where infants with prolonged bleeding or clotting times, or with clinical evidence of bleeding, have been treated directly. In these instances we have given 1 mg. doses, in oil, dropping the solution on the back of the tongue from a dropper or small syringe, without a needle. At first as much as 5 mg. in twenty-four hours was given; later this was reduced to 1 mg. every eight hours for twenty-four hours. In every instance the treatment has

been satisfactory, all clinical signs clearing up within twenty-four hours, and the prothrombin time returning to about the normal average. In one such case a prothrombin time of over ten minutes fell to twenty-five seconds within forty-eight hours after treatment started.

SUMMARY AND CONCLUSIONS

The average prothrombin clotting time of babies whose mothers were given synthetic vitamin K (2-methyl-1,4-naphthoquinone) by mouth during labor was much faster than the average of a similar untreated series, and close to the normal adult average.

From 15 to 50 per cent of the control series determinations made during the first six days were higher than the highest value in the treated series for the corresponding day.

One milligram of the vitamin in corn oil during the first stage of labor, four to ten hours before delivery, proved effective.

Three milligrams in twenty-four hours at eight-hour intervals, given direct to the baby by mouth, has been sufficient to control bleeding and reduce prolonged prothrombin clotting times to normal.

Administration of the synthetic vitamin K to women in labor has been adopted as a routine procedure at the Maternity Hospital and the Cleveland City Hospital.

BLOOD CHEMISTRY OBSERVATIONS IN LEUCEMIAS*

EVANS W. PERKINS, M.D., and M. R. FREELAND, Ph.D.
CHICAGO, ILL.

THE object of this paper is to report the blood chemistry findings on 9 patients with myelogenous leucemia, and 4 patients with lymphatic leucemia. Acute, chronic, and aplastic phases of the disease are represented.

It has been observed for years that when the blood of patients with leucemia is drawn from a vein and allowed to stand for a short time a white fatty layer, or a fatty turbidity develops. This seemed to bear no relationship to food taking, and the sera drawn twelve hours after a meal were often as turbid as those drawn after the patient had had breakfast. When the blood of patients with leucemia was spread on a slide for staining, it had a peculiar granular appearance not met with in any other type of blood dyscrasia. These observations led us to believe that in this disease there might be some dysfunction of the fat metabolism.

In 1925 Backman, Daland, and Weld reported some observations on the phosphorus content of whole blood, plasma, and cells. They concluded that in myelogenous leucemia there was an increase of the phosphorus in the whole blood due to the increased phosphorus in the cells and that the serum phosphorus remained the same. They also concluded that the total phosphorus content of the cells depended on the number of immature cells present. We felt that in addition to the increased phosphorus and phospholipids in the cells that there must also be an increase in the lipoids of the blood plasma and serum in order to produce the turbidity noted in oxalated blood and the granular appearance seen when making slides.

Due to the difficult methods for lipid determinations and the large volumes of blood required, it has been impossible to get complete determinations on all patients. We have, however, done cholesterol, cholesterol ester, lipid phosphorus, lecithin, total lipid, and fatty acid determinations. The results of the lipid determinations are listed in Table I. In addition we have done amino acid, inorganic calcium, phosphorus, and few nonprotein nitrogen determinations. Only two albumin and globulin ratios have been done.

All the determinations were done by one of us (M. R. F.) in the laboratories of the Presbyterian Hospital of Chicago. The methods used are the standard ones employed in the hospital laboratories and are listed in the references. Our results are summarized in Tables I and II. Table I dealing with lipid chemistry and Table II with the other observations that we were able to make.

10. A biologic assay on a three-day sample of urine of one of the myelogenous leucemia patients done through the courtesy of Dr. F. C. Koch in his laboratories showed: international units of androgen per day 15; estrogens as equivalent of theelin per day 12 gamma. The value for androgen is very low for normal males.

CONCLUSIONS

1. Total lipoids in all cases were greatly elevated, irrespective of the type of leucemia and the height of the blood count.

2. Total and esterified cholesterol determinations were normal in all but one case.

3. The inorganic calcium and phosphorus determinations were normal. Non-protein nitrogen determinations were normal.

4. Four amino acid determinations were normal, and one was elevated.

5. Fatty acids were elevated much above normal.

6. The difference between the total lipoids and the sum of the cholesterol, fatty acids, and phospholipid fractions was greater in all cases than the normally expected values for normal fats.

7. Lipoid phosphorus was elevated in only a third of the cases and did not bear a constant relationship to the height of the white count and the number of blast cells present.

Note.—Blood lipid determinations were all done by the Bloor method and were begun before the work of Christensen¹² and Van Slyke and Folch¹³ was published. This study of the lipoids in leucemias is being continued in our laboratories by both the Bloor method and the modifications suggested by the authors mentioned.

DETERMINATION OF BLOOD PYRUVATE IN VITAMIN B₁ DEFICIENCY*

PEI KUANG LI, M.D., AND KATSEJI KATO, M.D.
CHICAGO, ILL.

UNDoubtedly one of the most striking changes occurring in the tissues and body fluids in vitamin B₁ deficiency is the abnormal accumulation of carbonyl compounds, particularly pyruvic acid, as the result of incomplete or disturbed metabolism of carbohydrate, as demonstrated by Thompson and Johnson,¹ and by Johnson, Meiklejohn, Passmore, and Thompson.² Extensive investigations by Peters and his associates have led also to the hypothesis that vitamin B₁ functions as a coenzyme in the oxidative catabolism of glucose, particularly in the decarboxylation of pyruvic acid.³ Furthermore, Platt and Lu⁴ reported finding definite increases of bisulfite-binding substances, consisting chiefly of pyruvic acid, in the body fluids of persons with beriberi. From these and numerous other observations it is at once clear that the accumulation of pyruvic acid in the tissues and body fluids may be regarded as a specific "biochemical lesion" produced by a lack of vitamin B₁, and Cowgill⁵ suggests that quantitative examination of blood for pyruvate might be made the basis of a biochemical method for detection of a state of vitamin B₁ deficiency. The present series of experiments were undertaken to test the validity of this suggestion, and more specifically to find a simple and yet reliable method for the diagnosis of subclinical and clinical deficiency states in both man and animals.

EXPERIMENTAL PROCEDURES

For this experiment 12 normal rats were used, 6 males and 6 females, and each from a different litter. The males averaged 249 Gm. in weight, and the females 169 Gm. At the age of two months the animals were put on a synthetic vitamin B₁-free diet having the following composition:

Sugar	4,700 Gm.
Devitaminized casein	1,500 Gm.
Autoclaved liver	1,500 Gm.
Crisco	1,700 Gm.
Salt	250 Gm.
Cod-liver oil	300 c.c.

Each animal was kept in a separate wire cage with free access to a supply of distilled water contained in a clean inverted glass bottle. Daily inspection of general condition was supplemented by a semiweekly recording of body weight.

During the three days prior to the beginning of the devitaminized dietary regime, the blood pyruvate was determined in every animal, and the value so obtained was regarded as the normal basal level for that particular animal.

*From the Department of Pediatrics, University of Chicago.
Received for publication, June 13, 1940.

During the entire period of experiment, extending over sixty days, the concentration of blood pyruvic acid was determined at weekly intervals. At the peak of avitaminosis, as evidenced by a pronounced increase in blood pyruvate and by the appearance of paralytic symptoms, a single dose (30 international units) of crystalline thiamin hydrochloride in aqueous solution was injected intraperitoneally. The changes in the level of blood pyruvic acid were then followed at intervals of two, four, six, eight, and twenty-four hours following the injection.

In order to ascertain the possible effect of inanition on the concentration of blood pyruvate, another group of 6 healthy rats, 3 males and 3 females, was put on an absolute starvation regime, allowing only an adequate supply of distilled water. The determinations of pyruvic acid in the blood of these animals were made at the end of twenty-four, forty-eight, and seventy-two hours. No further examinations were attempted inasmuch as after two days of starvation the values remained unaltered.

The average normal values of blood pyruvate in rats were obtained from 30 normal animals, equally distributed between the two sexes, and of different ages and litters.

All blood samples for chemical analysis were obtained from a cut in the tip of the tail made with a sharp razor blade. Since exercise, muscular effort, and emotional excitement are known to influence the pyruvate picture, the animal was first wrapped in a piece of soft cloth and then placed in a small wooden box. A small circular opening was provided at each end of the box, the one in the front for ventilation and the other in the back for permitting the tail to protrude. The animal so placed in the box was allowed to rest for at least one hour before the blood was withdrawn.

CHEMICAL METHODS

From the time of the discovery of pyruvic acid by Berzelius⁶ in 1835, no less than sixty different methods for its identification and estimation have appeared in the literature, according to the reviews published by Wendel⁷ and by Lu.⁸ However, only a few of these are applicable to clinical usage for blood analysis, and of these the following are noteworthy:

(1) The bisulfite-binding substance (B.B.S.) method of Clift and Cook⁹ is based on the property of the carbonyl compounds to react to bisulfite. This reaction, however, is not specific for pyruvic acid, since methylglyoxal, acetaldehyde, formaldehyde, and other ketonic acids also give the same positive reaction.

(2) The nitroprusside method of Simon and Piaux¹⁰ is generally believed to be specific for pyruvic acid, but the procedure is unsuitable for accurate quantitative analysis in the opinion of Platt.¹¹

(3) The 2,4-dinitrophenylhydrazine method of Case¹² is based on the characteristics of pyruvic acid to form hydrazone, and its solution in alcoholic potassium hydroxide is determined colorimetrically against a standard. The method, earlier used by Nenberg and Kobel,¹³ and later modified by Peters and Thompson,¹⁴ is specific for pyruvic acid; but it necessitates the use of a large amount of blood, and the length of time required to complete such an analysis makes its employment inadvisable for clinical purposes, especially if one is working with small subjects.

(4) The recently reported method of Lu,^s essentially a rapid and micro-modification of the Case-Nenberg technique, has by trial been found to be not only specific for pyruvic acid but admirably suited as well for use in clinical laboratories, especially in infants' and children's hospitals. These advantages commend themselves to experimental work in which small animals (rats, rabbits, and guinea pigs) are used. This method has been employed throughout the present investigation, the principal steps of which follow:

From a fresh cut on the tip of the rat's tail approximately 0.2 c.c. of blood is obtained and quickly dropped into a centrifuge tube containing exactly 1 c.c. of a 10 per cent solution of trichloroacetic acid which has been previously weighed and kept at a low temperature in a vessel packed with finely shaved ice. After mixing the clotted blood thoroughly with the acid by means of a fine glass rod, the actual amount of blood is calculated by reweighing the test tube and comparing its present weight with that prior to introduction of the blood.

Complete precipitation of blood proteins is allowed to take place at this low temperature for fifteen to twenty minutes, and then the tube is centrifuged for five minutes at high speed (1,500 to 2,000 r.p.m.). The clear supernatant fluid containing pyruvic acid is carefully transferred to a clean test tube (tube 1) by means of a long glass pipette. The precipitate is again treated with 1 c.c. of a 5 per cent solution of trichloroacetic acid and, after reagitation, is allowed to stand for five minutes at low temperature to remove the remaining portion of pyruvic acid. The supernatant fluid obtained after centrifugation is added to the contents of tube 1.

One cubic centimeter of a 0.1 per cent solution of 2, 4-dinitrophenylhydrazine solution in 2 N hydrochloric acid is next added to tube 1 and allowed to react at room temperature for at least ten minutes, for the complete formation of a hydrazone of pyruvic acid. The resulting hydrazone is then extracted with 2 c.c. of ethyl acetate, by first aspirating the latter up into the pipette and then expelling it into the layer of hydrazone at the bottom of the tube. By repeating the process several times a final homogeneous turbid mixture will be obtained. After standing a few minutes the bottom layer is then pipetted off into tube 2, the remaining acetate solution being kept in tube 1.

Another 2 c.c. portion of ethyl acetate is then added to tube 2 and extraction of hydrazone is repeated as before. The bottom layer, which becomes water-clear upon complete separation of the two layers, is discarded, and the remaining acetate solution is carefully transferred to tube 1.

The inner surface of tube 2 is rinsed with 2 c.c. of a 10 per cent solution of sodium carbonate, and the contents of the tube are then poured into tube 1. By means of the same pipette the top layer of the acetate is thoroughly mixed with the bottom layer of sodium carbonate. When the two layers are completely separated, the bottom layer is transferred back to tube 2. The same procedure for extracting pyruvic acid with sodium carbonate solution is repeated for the second and third times, the sodium carbonate layer being each time transferred to tube 2. The final acetate remaining in tube 1 is discarded, and the three extractions of pyruvic acid in sodium carbonate in tube 2 now total 6 c.c. in volume.

The final removal of a trace of hydrazone of ketonic acids other than pyruvic acid is made by the addition of 1 c.c. of ethyl acetate to tube 2. When the two layers are clearly separated, the yellow-colored bottom layer is carefully transferred to tube 3.

Four cubic centimeters of a normal sodium hydroxide solution are added to tube 3. The reddish color which then develops almost instantaneously will fluctuate somewhat if any impurities happen to be present in the mixture; and if so, color due to substances other than pyruvic acid will disappear within ten minutes. While allowing these ten minutes to elapse, the photoelectric cell colorimeter (Evelyn) is in the meantime being warmed to its optimal working condition. The unknown solution is then transferred to a colorimeter cell and, using filter 520, a galvanometer reading is recorded. The amount of pyruvic acid is calculated from a standard curve previously prepared by calibration of pure solutions of pyruvic acid (redistilled three times) in triple distilled water, in accordance with the directions given by Lu.⁸

RESULTS OF ANALYSES

The data obtained from blood analyses by the micromethod of Lu, as outlined and presented in Table I and Charts 1 and 2, comprise: (1) normal pyruvic acid values in the blood of rats, (2) pyruvate picture in various stages of vitamin B₁ deficiency, (3) blood pyruvic acid determinations in starvation, and (4) effect of thiamin on blood pyruvate in vitamin B₁-deficient rats.

As seen from Table I, the average normal value for blood pyruvic acid in 30 healthy rats, equally distributed between the two sexes, and ranging in age from two months to eight months, was 0.91 mg. per cent for the entire group. The maximum values were from 1.20 mg. per cent for females and 1.30 mg. per cent for males; the minimum figures varied from 0.50 mg. per cent for females to 0.60 mg. per cent for males. The standard deviations, as calculated from the equation, $D.S. = \sqrt{\frac{\sum m^2 - M^2}{N}}$, were ± 0.03 for females and ± 0.05 for males.

The data presented in Chart 1 depict the fluctuations in concentrations of blood pyruvate in 12 experimental animals at various stages of vitamin B₁ deficiency. The basal values in these animals were obtained within the three days prior to initiation of vitamin deprivation. That pyruvic acid progressively accumulates in the blood in direct proportion to the increasing severity of the deficiency state is evident. So much so, in fact, that by the end of the eighth week of observation, and coincident with the development of neurologic signs, the increase amounted to almost 500 per cent of the basal value.

One complicating factor affecting the pyruvic acid level of the blood in avitaminous rats is the influence of inanition, since in the majority of experimental animals on vitamin B₁-deficient diet anorexia was usually pronounced. In order to ascertain the effect of starvation, 6 healthy rats (3 males and 3 females) were deprived of all food and given a generous supply of distilled water. Determinations of blood pyruvate were made at the end of twenty-four, forty-eight, and seventy-two hours following the institution of starvation regime. From the data so obtained, and presented in Table I, it is clear that

inanimation produces a moderate increase in blood pyruvic acid values. These findings confirm the observations recorded by Lipschitz, Potter, and Elvehjem,¹⁵ who found the liver's ability to remove added pyruvate to be seriously impaired in fasting.

TABLE I

24	2.43
48	3.15
72	2.70

The remarkably rapid and decisive influence of a single intraperitoneal injection of thiamin hydrochloride, in the calculated minimal dose (30 international units) for producing a state of saturation as recommended by Leong,¹⁶ is brought out in the data summarized in Chart 2. As revealed by these data, the action of thiamin in these animals is reflected within two hours after the injections, the blood pyruvate values dropping promptly to the extent of about 50 per cent of the preinjection level. At the end of four hours following injections, general condition of the animals was markedly improved, yet in each animal at this stage the blood pyruvate values were definitely elevated. This phenomenon may be explained on the ground that thiamin produces greatly accelerated activity of the animal. Increased activity, in turn, requires a more adequate liberation of phosphorylated thiamin, or cocarboxylase, by the cells in order to cope with the increased metabolism of the ketonic acid. By the eighth hour following injections the blood pyruvate usually had dropped nearly 65 per cent. One animal of this group, which failed to exhibit this typical response to thiamin at this stage, died about ten hours later. Platt¹¹ reported a similar observation in some cases of human beriberi. At twenty-four hours after injections the pyruvic acid of the blood remained at practically the same low level as in the previous examination. The clinical improvement was also remarkable, the only residual signs of deficiency being emaciation and spasticity of limbs.

DISCUSSION

According to Barron,¹⁷ pyruvic acid is an extremely reactive substance, having possibilities of undergoing at least fifteen different biochemical reactions, either with or without the catalytic action of thiamin and its pyrophosphoric ester. Thus the reactions of this ketonic acid, as characterized by reduction, couple oxidation-reduction, amination and transamination, proceed without intervention of vitamin B₁, whereas reactions such as oxidation, dismutation, and decarboxylation require its presence. From the work of Barron and Lyman¹⁸ the following statements may be quoted: "Under optimal conditions for oxidation, the pyruvic acid is directly oxidized to acetic acid and CO₂; under optimal conditions for reduction it may be reduced to lactic acid or may be split by dismutation into acetic acid and formic acid. . . . The direction and the extent of these reactions will be determined by the value of the constants of the equilibrium reactions taking place under the conditions of the experi-

Chart 1.—Scattergram showing increasing values of blood pyruvate in direct proportion to progress of deficiency in rats.

Chart 2.—Effect of intraperitoneal injection of thiamine hydrochloride on blood pyruvate level in vitamin B₁-deficient rats.

ment." These significant statements reveal the fundamental principle by which vitamin B₁ therapy should be applied in clinical practice.

While as yet no single system of glycolytic cycle has been satisfactorily established by either in vivo or in vitro experiments, pyruvic acid is now generally looked upon as a normal intermediary product of carbohydrate metabolism. It is formed by the splitting of the glucose molecule with the mediation of diphosphopyridine nucleotide during the process of glycolysis as well as in alcoholic fermentation. The degradation of pyruvic acid so formed proceeds by means of the catalytic action of thiamin in its phosphorylated form, known as cocarboxylase or diphosphothiamin. From recent investigations of Goodhart and Sinclair¹⁹ it appears clear that vitamin B₁ circulates in plasma in the form of a free unphosphorylated thiamin which diffuses readily into the cells and passes out into the tissue fluid. Phosphorylation of the vitamin with the formation of cocarboxylase occurs within the cells. In the blood there is but little free vitamin B₁ or cocarboxylase, most of it being combined probably with specific protein, according to the work of Sinclair.²⁰ Normal human blood contains an average of 7.0 micrograms per cent of carboxylase, mostly in combined form.²¹ In the absence or in the definite diminution of this vitamin, therefore, the removal of pyruvic acid is greatly retarded. This retardation in the rate of pyruvate disposal is responsible for its accumulation within the tissues and body fluids; the resulting "pyruvic acid acidosis," which is a specific biochemical lesion of avitaminosis B₁, is a measure of this deficiency.

Thus for diagnosing a possible vitamin B₁ deficiency state a direct estimation of either thiamin or cocarboxylase is logically the accurate measure. However, owing to the fact that the actual amount of thiamin or of diphosphothiamin present in the blood is small, and especially so in avitaminosis, the direct measurement is more difficult to perform than is the indirect estimation made by determining the concentration of blood pyruvic acid. In fact, the data obtained from animal experimentation here presented conclusively demonstrate pyruvic acid determination to be a simple and yet reliable measure of vitamin B₁ deficiency. By this means not only the accurate diagnosis of the clinical type of deficiency is possible, but also the identification of the subclinical type is easily demonstrable. The clinical application of this procedure for the diagnosis of vitamin B₁ deficiency in human beings will be reported in a subsequent communication.

SUMMARY AND CONCLUSIONS

The accumulation of the bisulfite-binding substances, particularly pyruvic acid, in the body fluids of avitaminous animals appears to play a significant role in the pathogenesis of symptom complex associated with vitamin B₁ deficiency. The present investigation was undertaken to ascertain whether or not estimation of pyruvic acid in the blood, rather than direct determination of thiamin or its cocarboxylase, could be used as a suitable method for the diagnosis of subclinical as well as clinical vitamin B₁ deficiency.

The results of chemical analyses for pyruvic acid in the blood of experimental animals (rats) by the use of the specific micromethod (2,4-dinitrophenylhydrazine) as reported by Lu⁸ indicate that by the end of the first

month of thiamin depletion the amount of blood pyruvate increased more than 260 per cent (3.49 mg. per cent) over the normal basal level (0.96 mg. per cent). During the second month the increase was almost 500 per cent (5.62 mg. per cent). Shortly before death there was usually a remarkable accumulation of pyruvic acid in the blood of thiamin-deficient animals. The magnitude of blood pyruvate appears to correspond roughly with the severity of clinical manifestations, since during the first month the only noticeable signs of avitaminosis were loss in weight, weakness, and anorexia; but during the second month definite neurologic symptoms began to develop. Upon injections of thiamin hydrochloride in these polynuritic animals a prompt fall in blood pyruvate occurred. If the injection of thiamin is not followed by this characteristic drop in blood pyruvate, death within twenty-four hours may be expected.

THE ABSORPTION OF NICOTINE FROM CIGARETTE SMOKE*

I. H. PIERCE, IOWA CITY, IOWA

ALTHOUGH many papers reporting work on the composition of cigarette smoke have been published, the question of the exact amount of nicotine absorbed in the smoking of a cigarette has, for the most part, escaped attention. Sollmann¹ states, "Between 15 and 90 per cent of the nicotine present in the tobacco are recovered from the smoke but a greater part of this is exhaled or expectorated." This statement apparently refers to pipe or cigar smoking, for in the same paragraph the author says, "In cigarette smoking, where inhalation is commonly practiced, the percentage absorbed would be relatively high." To quote from Asherson,² "the average cigarette contains 19 mg. of nicotine; in the portion actually smoked, about 14 mg., of this about 7 mg. enters the mouth." Lehmann³ found that about 5 mg. of nicotine was absorbed when the smoke from one cigarette was deeply inhaled.

Since nicotine is extremely soluble in water and almost nonvolatile at body temperature, it would seem remarkable if it would escape being retained in a very high degree when brought in contact, as it is in the inhalation of cigarette smoke, with the very large surface of the respiratory tract. The purpose of this study is to ascertain the amount of nicotine absorbed from cigarette smoke under conditions as nearly as possible like those present in ordinary smoking.

EXPERIMENTAL

Three brands of cigarettes were used: No. 1, a popular, medium-priced American cigarette, had a nicotine content of 2.27 per cent. No. 2, a so-called Egyptian cigarette, had a nicotine content of 1.16 per cent. No. 3, hand-rolled cigarettes made from a low-priced granulated tobacco, had a nicotine content of 2.63 per cent. All nicotine contents are based on dry weight of tobacco.

An absorption train was set up consisting of six ammonia-absorption tubes containing tenth-normal sulfuric acid. The cigarette was placed in a glass holder on the intake end and smoked by applying suction by mouth at the other end so as to draw the smoke into the train. Suction was applied at intervals, approximating as closely as possible the frequency, duration, and depth of inspiration employed in natural smoking. Ten aspirations were employed, since observation of smokers indicated that most of them draw about ten times while smoking a cigarette. That the aspirations were quite uniform was shown by the fact that the nicotine in the smoke from 5, 10, and 15 inspirations proved to be almost exactly in the ratio 1:2:3. The smoke thus inhaled is designated as the

*From the Department of Pharmacology, College of Medicine, State University of Iowa.
Received for publication, June 13, 1940.

"main stream." In some experiments the smoke escaping from the burning tip was drawn off continuously through a second absorption train and is herein designated as the "side stream."

For determining the nicotine in the exhaled smoke, the following procedure was adopted: Air was drawn continuously through the train by a suction pump, and the smoke from the cigarette, after being deeply inhaled, was blown into the intake end. The exhaled smoke from ten deep inhalations was collected, the respiratory tract being ventilated after each exhalation by taking several deep breaths and exhaling into the train. In some experiments the smoke, instead of being deeply inhaled, was only drawn into the mouth, held for a few seconds and expelled. The nicotine absorbed is the difference between that in the main stream and that in the exhaled smoke.

Altogether, nicotine was determined in the cigarettes, the stubs, the main stream, the side stream, and the exhaled smoke. The cigarettes and stubs were extracted by the Kissling method, with final precipitation with silicotungstic acid. The smoke solutions were evaporated to a small volume, made alkaline, and the nicotine was distilled in a current of steam and precipitated with silicotungstic acid. Pyridine, in the amounts present in cigarette smoke, does not interfere.

DATA

There is some condensation of vaporized nicotine in the stub. The average nicotine content of the stubs of 50 cigarettes was 2.57 per cent, while that of the cigarettes was 2.27 per cent.

The distribution of nicotine between the stub, the main stream, the side stream, and that destroyed is shown in Table I.

TABLE I
AVERAGES FROM 20 CIGARETTES, BRAND NO. 1, 10 INHALATIONS
Nicotine in Milligrams

IN CIGARETTE	IN STUB	IN SMOKE		DESTROYED
		MAIN STREAM	SIDE STREAM	
27.43	11.91	3.88	4.31	3.83

The distribution is, of course, affected by tightness of rolling, moisture content, and the manner in which the tobacco is cut, as well as by the duration and force of aspiration.

The results of the experiments on absorption by deep inhalation are shown in Table II.

TABLE II
AVERAGES OF 50 CIGARETTES, 10 DEEP INHALATIONS

BRAND NO.	NICOTINE %	NICOTINE					
		IN CIGARETTE (MG.)	IN STUB (MG.)	IN INHALED SMOKE (MG.)	IN EXHALED SMOKE (MG.)	ABSORBED	
						MG.	IN % OF NICOTINE INHALED
1	2.27	23.2	12.27	3.74	0.17	3.56	95.0
2	1.16	11.65	6.16	2.76	0.15	2.61	91.6
3	2.63	25.1	14.75	2.60	0.32	2.28	87.8

When the smoke is not deeply inhaled, but only drawn into the mouth and expelled after two seconds, the absorption is distinctly less, as shown in Table III.

TABLE III

AVERAGES OF 50 CIGARETTES, BRAND NO. 1, SMOKE DRAWN INTO MOUTH ONLY AND EXPELLED AFTER 2 SECONDS. 10 INHALATIONS

NICOTINE			
IN INHALED SMOKE (MG.)	IN EXHALED SMOKE (MG.)	ABSORBED	
		IN MG.	IN % OF NICOTINE INHALED
3.74	0.85	2.89	77.3

The absorption of total solids was determined in the same manner as was that of nicotine, except that the smoke was absorbed in tenth-normal hydrochloric acid, the solutions evaporated to dryness, and the residues weighed. The results appear in Table IV.

TABLE IV

ABSORPTION OF TOTAL SOLIDS. AVERAGE OF 20 CIGARETTES, BRAND NO. 1, 10 DEEP INHALATIONS

IN INHALED SMOKE (MG.)	IN EXHALED SMOKE (MG.)	ABSORBED	
		IN MG.	IN %
26.4	8.4	18.0	68.2

DISCUSSION

These results show that of the nicotine present in the burned tobacco, about one-third is drawn into the mouth when a cigarette is smoked in the manner employed in these experiments. This figure probably represents the maximum amount, for the inspirations were as deep as possible to secure uniformity.

These experiments do not bear out the general impression that only a small fraction of the nicotine inhaled is absorbed. They show, on the contrary, that over 90 per cent is absorbed when the smoke is deeply inhaled and not much less when it is only drawn into the mouth.

The smoking of one package of 20 cigarettes of brand No. 1, under the conditions of these experiments, represents the absorption, with deep inhalation, of 71.4 mg. of nicotine, or without the inhaling of the smoke into the lungs, of 57.8 mg. If a smoker consuming one package of cigarettes a day can continue the absorption of this amount of nicotine over a long period of time without deleterious effects, it indicates either the establishment of a very high degree of tolerance to the effects of nicotine or that the toxicity of this alkaloid in the human being is very much lower than that indicated by minimum lethal doses as determined on animals.

The high degree of absorption of total solids is also of importance. These solids contain, besides nicotine, resinous and tarry substances, such as phenols, cresols, creosols, etc., ammonium salts, and other constituents in small amount. These undoubtedly contribute to the irritating effect of the smoke.

SUMMARY

When cigarette smoke is inhaled deeply, over 90 per cent of the nicotine in the smoke is retained in the respiratory tract.

If the smoke is not inhaled, but is drawn only into the mouth and expelled, about 77 per cent is retained.

The total solids of the smoke are retained to the extent of about 68 per cent.

THE APPEARANCE OF BLOOD BROMIDE AFTER ORAL INGESTION*

FREDERICK B. FLINN, NEW YORK, N. Y.

THE enactment of the Pure Food and Drug Law has brought many problems not only to the Government Bureau in charge of the enforcement of the act, but also to the manufacturers of self-medication products. Outstanding among these problems are those concerned with recommended doses and proper warnings as to possible dangers which may arise from incorrect use of many of the self-medication products on the market. Among the drugs which have received attention are the bromides, since they are contained in many preparations for the relief of minor headaches and pains.

Ten to fifteen grains of bromide several times a day has been considered a safe therapeutic dose when taken under the supervision of a physician. In epileptic cases as much as 10 to 15 Gm. have been given over a period of years without any untoward effects. These large doses are not given at the beginning of the treatment but are attained by gradually increasing the daily dose. It is generally recognized that a rash may appear from the use of bromides in allergic persons. This rash apparently has no relationship to the dosage taken and disappears rapidly when the medication ceases. However, the rash, together with persistent drowsiness, has been suggested as an early warning that the medication should be stopped.

It was to determine the effects of daily doses over a period of weeks that the present study was undertaken. It is stated in the literature that no harmful effects appear in bromide treatment until the blood bromides reach 200 mg. per hundred cubic centimeters of blood. Because of this theory, we used the blood bromide as an indication of the possible danger that might arise from taking the drug. In our study we used sodium bromide entirely, although both the ammonium and potassium salts are frequently employed. We are reporting on these in a later paper.

A group of 70 adults, ranging from ages 21 to 61, volunteered for our study. To assure that they would remain faithful to the study which lasted

*From the Delamar Institute of Public Health, Columbia University, New York.
Received for publication, July 31, 1940.

five months, they each received a nominal monthly fee and at the end of the study took an oath before a notary that they had carried out all of our instructions. No attempt was made to obtain only healthy persons in accepting the volunteers. The group contained several alcoholics. We felt that it was a representative cross section of the population. It consisted of college students, housewives, laboratory assistants, laboratory workers, clerks, artists, artist models, watchmen and janitors, and doctors.

Each individual received a careful physical examination at the beginning of the study, and at the end of the second and fourth months by a competent medical man who had no contact with them at any other time. Special attention was paid to the following factors: nervous reactions; reaction time to light signals; electrocardiogram; oxygen capacity; carbon dioxide capacity; hemoglobin; bromides in blood at the end of two, four, and five months, respectively; urine bromides; and changes in the white and red blood cell counts. The blood gases and hemoglobin were determined by the Van Slyke method.

For the determination of bromides we adapted the method of Katzenelbogen and Goldsmith,¹ based on the reaction of brown gold chloride with bromide, the quantity being estimated colorimetrically. Certain modifications were made in the quantities of reagents used. Four cubic centimeters of blood were added to 7 c.c. of 0.75 per cent sodium chloride solution and 3.4 c.c. of 20 per cent trichloroacetic acid and allowed to stand for one-half hour. The solution was then filtered. One cubic centimeter of a 0.5 per cent acid brown gold chloride solution was added to 5 c.c. of the filtrate and mixed well. The color was read in the Zeiss Pulfrich Photometer with a green Zeiss filter S53. The quantity of bromide present in 100 c.c. of blood was read from a curve derived from known blood bromide solutions. From time to time we checked the results by the Brodie and Friedman² method. The gold bromide method was purposely used because practically all the results reported in the medical literature are obtained by the Wuth method. It is conceded that this Wuth method is not a scientific method and does not give absolute results, but it is a good clinical method within certain ranges.

We divided the group into two sections: one consisting of 55 persons taking a total of 30 grains of bromides three times daily, the other consisting of 15 persons taking 15 grains three times daily. The bromides were taken each day, seven days a week for four months, and then stopped. The persons were examined at the end of the fifth month to see whether there was any difference in their physical condition and how much bromide still remained in the blood.

Since we could not detect any significant changes in the subjects, we are tabulating in Table I only our average findings.

A glance at Table I shows that there were no changes in the blood gases or blood cell counts. The same can be said for pulse rate and blood pressure. The electrocardiograms were negative throughout the study. The reaction time to light stimulation did not show any increase. In the case of the students we were able to obtain a record of their standing before the test began and at the end. These records showed that there was no lessening of their intellectual capacity; to the contrary there was a slight improvement. It is hard to make such a comparison, for the courses vary in different terms and one term's work may be easier than another.

Twenty-five of the group taking 30 grains daily over the four-month period were given a very careful examination by three well-known neurologists immediately after the medication had ceased. They pronounced the group to be normal in every way and expressed the opinion that they could serve as a control group in any study we would want to make.

No reports of drowsiness were received from the groups, and in only two persons was a rash observed. In one of these the rash was furunculosis, and in the other, a young lady, it was acne; it was rather hard to say whether this was due to the bromide or to the warm weather since the examination took place in August.

Our most interesting observation was the wide variation in the amount of bromides found to be present in the blood of various individuals. In some individuals this was approximately normal and in others it was much higher. The highest quantity found in our subjects was 89.6 mg. per 100 c.c. of blood at the end of four months. The average in the group taking 30 grains daily was 16.55 mg. In the group whose daily dosage was 45 grains, it was 50.09 mg. The same individual variations were noted in our animal experiments which are being reported in another paper. In the case of the smaller dose it would appear that the organism soon learns to handle the bromide and the blood level settles down to a more or less constant quantity. The individual differences may be accounted for by the variations in the amounts of sodium chloride taken by the individuals. It has been estimated in heat studies that the daily ingestion of salt varies from

TABLE IV

Cat 1 1 hour	Original solution contained	310.50 mg. bromide
	Recovered at end of 1 hour	215.46 mg. bromide
	Bromide absorbed	95.04 mg. bromide, or 30.6 per cent
Cat 2 2 hours	Original solution contained	313.20 mg. bromide
	Recovered at end of 2 hours	153.80 mg. bromide
	Bromide absorbed	159.30 mg. bromide, or 50.9 per cent
Cat 3 1 hour	Original solution contained	315.00 mg. bromide
	Recovered at end of 1 hour	230.85 mg. bromide
	Bromide absorbed	84.15 mg. bromide, or 26.7 per cent

10 to 20 Gm. There may be some explanation for the variation by rate of absorption from the gastrointestinal tract. In order to determine whether the time at which bromide was taken previous to the drawing of the blood was a factor, careful notation was made when the last dose was taken before the blood was drawn. The blood was taken, as a rule, between 9:30 A.M. and noon. Table II gives the results of this observation.

To determine how soon bromide could be detected in the blood after it was ingested, two of our technicians each took 3 Gm. in one dose. Samples of blood were drawn at frequent intervals throughout the day and samples of urine were collected at the same time. The results, shown in Table III, were somewhat of a surprise to us; they also showed the individual variations.

Three cats were anesthetized with nembutal. The abdomen of each was opened and a segment of the intestine was tied off. A cannula was inserted in either end of the segment, and the segment was washed out with a 0.6 per cent sodium chloride solution. The saline solution was then removed. The lower end of the segment was clamped off and a measured quantity of 0.90 per cent sodium bromide solution was permitted to flow into its upper end. The upper end was then clamped off, and the intestine was placed back in the abdominal cavity. It was allowed to remain there for one hour in two cats, and for two hours in the third cat. The segments were then washed out and analyzed for bromide. The results are indicated in Table IV.

In discussing our study with physicians, we were told that they have noted the same type of variations among their patients. Our observations indicate that after the medication has continued for a few weeks, the blood bromide tends to drop to a lower level and remain there. It is necessary to increase the quantity of sodium bromide ingested to get a higher blood bromide. This has been definitely indicated in our animal work and will be reported soon.

SUMMARY

1. The ingestion of 30 to 45 grains of sodium bromide daily over a period of four months does not result in a high blood bromide.
2. The blood bromide drops rapidly after the medication stops.
3. The ingestion of 30 to 45 grains of sodium bromide daily over four months does not affect the blood picture.
4. The ingestion of 30 to 45 grains of sodium bromide daily over a four-month period does not affect the nervous reactions.

HIPPURIC ACID LIVER FUNCTION TEST: INTRAVENOUS METHOD*

ELMER C. BARTELS, M.D., BOSTON, MASS.

OUR experience with the oral hippuric acid test for liver function in determining the status of the liver in hyperthyroidism has been reported.¹ The test revealed reduction in the liver function in a high proportion of cases. Of the 148 patients studied, only 18 gave a normal response. The degree of change in the liver function was in fair proportion to the severity of the hyperthyroidism as determined by the basal metabolic rate and the clinical opinion as to the necessity for one or two operations. The value of the hippuric acid test as a satisfactory method of determining the function of the liver has been accepted by many investigators.²⁻⁷

About a year ago, at the suggestion of Dr. Quick, we began using the intravenous modification of the hippuric acid test. The test consists of the intravenous injection of 1.77 Gm. of sodium benzoate which has been dissolved in 20 c.c. of water. The urine is collected at the end of one hour and the hippuric acid content is determined. The normal excretion has been determined to be 1.77 Gm. or 0.7 Gm. of hippuric acid equivalent of benzoic acid.

A recent report by Quick⁸ gives in detail the procedure as employed in his laboratory. The test has much in its favor because of its simplicity. The fact that only one hour is required is an improvement, since the oral method requires four hours. We have now used the test over 300 times with the patient suffering only the slightest reaction or discomfort. At times there has been a slight flushing of the face and occasionally a sense of burning in the arm, but no other ill effects have been noted. Many difficulties encountered in the oral test, such as nausea and vomiting, and possible lack of absorption of the sodium benzoate from the stomach are overcome in utilizing the intravenous route. Patients have hesitated to cooperate in running serial tests by the mouth method because of the prevalence of nausea. The intravenous test has been carried out daily on the same patient without complaints.

The results of the intravenous tests in 58 patients with hyperthyroidism are given in Table I. Taking above 0.7 Gm. of benzoic acid as normal, we find only 7 patients (12 per cent) having satisfactory liver function. The remaining patients had hippuric acid excretions distributed throughout a wide range, to as low as 0.1 Gm., which is one-seventh the normal, and indicative of serious liver impairment. No correlation was found to exist between the level of the basal metabolic rate and the degree of disturbance of the liver function, as was found in our previous study utilizing the oral test. The duration of the hyperthyroidism and the weight loss were not related to the hippuric acid excretion.

*From the Department of Internal Medicine, The Lahey Clinic, Boston.
Received for publication, October 4, 1940.

Most significant in judging the clinical opinion of the toxicity of the patient with hyperthyroidism is the final conclusion of the medical and surgical staff as to the type of operation the patient will most likely tolerate. This opinion is reached by a correlation of observations on the patient which cannot be appraised statistically. It can be seen from the chart that as the liver function decreased the number of operations apparently increased. This observation held true in our previous study with surprising regularity. Therefore, in spite of the failure of the test to show a close relationship to the basal metabolism, duration of disease, and average weight loss, it seems to be grossly indicative of even a more important conclusion, and that is the number of operations to which the patient should be submitted. In this way the liver function in hyperthyroidism plays an informatory role in the general medical survey. As has been shown in our previous studies, the level of the liver function was in no way related to the postoperative reaction. The basis of the postoperative thyroid storm still remains unexplained. It probably is not the result of alteration in the liver function as has been suggested by some authors who call thyroid crisis a liver reaction (liver death).

TABLE I

LIVER FUNCTION IN HYPERTHYROIDISM: INTRAVENOUS HIPPURIC ACID TEST

RANGE OF EXCRETION (GM.)	NUMBER OF CASES	AVERAGE B.M.R.	AVERAGE DURATION OF DISEASE (MONTHS)	AVERAGE WEIGHT LOSS (POUNDS)	NUMBER OF PATIENTS AND OPERATIONS

Liver Function in Other Thyroid Conditions.—Patients with adenomatous goiter without hyperthyroidism showed normal hippuric acid excretions. In one patient with subacute thyroiditis with slight fever there was a slight reduction to 0.65 Gm. One patient with chronic myxedema had still greater reduction with an excretion of 0.42 Gm. One patient with therapeutic hyperthyroidism, who took 6 grains of desiccated thyroid a day in an effort to reduce weight, had an excretion which was a little more than one-third normal, 0.27 Gm. This patient shows evidences of the depleting effect of hyperthyroidism on the liver and also seems to indicate the fact that the test determines functional impairment since it is highly probable or almost certain that with the discontinuance of the desiccated thyroid the liver function in this patient will return to normal. This we determined to be true in clinical hyperthyroidism.

Primary Liver Disease.—In Table II the sample results of the test in diseases primarily affecting the liver are given. In all cases of cirrhosis of the liver a reduced function was found, in most instances to a marked degree. The same was true in the other cases of liver disease, which were the result of either in-

fection, chemical toxicity, or neoplastic infiltration. In catarrhal jaundice alone, which we do not recognize as producing intrinsic liver disease, the liver function was practically normal. Strangely enough, in three of four cases of chronic alcoholism, not recorded in Table II, in which no apparent physical or laboratory defects could be ascertained, the liver function (0.65, 0.64, 0.74, 0.67 Gm.) was only slightly altered in three instances.

TABLE II
LIVER FUNCTION BY INTRAVENOUS HIPPURIC ACID TEST
DISEASES OF THE LIVER

A. Cirrhosis	
Number of cases studied, 11	
Range of hippuric excretion	
0 to 0.40, 8 cases	
0.40 to 0.5, 2 cases	
	Hippuric acid excretion, Gm.
B. Cholangitis, 1 case	0.29
C. Primary carcinoma of liver, 1 case	0.16
D. Amoebic abscess of liver, 1 case	0.39
E. Arsphenamine hepatitis, 1 case	0.11
F. Catarrhal jaundice, 1 case	0.68
G. Metastatic infiltration of liver, 2 cases	0.40 to 0.12

Miscellaneous Diseases.—In a group of 5 patients with idiopathic splenomegaly, the test gave normal results varying from 0.68 to 0.88 Gm. In exogenous obesity equally normal results were obtained, irrespective of the degree of overweight. In chronic infectious arthritis there was a uniform reduction in the hippuric acid output to about 25 per cent. This reduction is apparently the result of the effect of the strain of detoxification on the liver.

One person with severe muscular dystrophy was tested, with a normal result, the excretion being 0.8 Gm. This result is significant as one criticism of the hippuric acid test has been the possible assumption that it may be the summation of the conjugation of sodium benzoate with glycine in both the liver and muscle. If this were true, a reduction in function should have resulted in this case.

The depleting effect of anesthesia on the liver is now under investigation. A number of investigators have reported the deleterious effect of various anesthetics on the liver. In the cases studied so far the hippuric acid excretion dropped 23 per cent on the day of the operation, with a gradual return toward normal on the third postoperative day.

CONCLUSIONS

1. The intravenous hippuric acid test of liver function has been used in a large group of patients without subjective or objective reactions. The simplicity of the test is noted. The results in a group of patients with hyperthyroidism compare favorably with the results previously reported in this condition in which the sodium benzoate was given by mouth.

2. In intrinsic liver disease the degree of reduction in the hippuric acid excretion is in direct accord with the clinical and autopsy findings as to the liver damage. This finding speaks favorably for the test.

3. The fact that repeated tests can be carried out without ill effects increases the value of the test.

THE HYPERPHOSPHATASEMIA OF PAGET'S DISEASE*

H. L. WILLIAMS, B.A., M.S., AND E. M. WATSON, M.D., LONDON, CANADA

THE serum phosphatase activity is characteristically increased in persons with Paget's disease of bone. Different opinions have been expressed with regard to the nature of this hyperphosphatasemia. For example, Kay¹ relates the high values to an excess of phosphatase in the blood due to the diffusion of the enzyme from the sites of formation in the bones at rates above the normal. On the other hand, Thannhauser and co-workers,^{2, 3} on the basis of their experiments, and the observations of Freeman and Chen,⁴ conclude that the increased serum phosphatase activity found in pathologic conditions, including Paget's disease, is due to the presence of an activator of the enzyme in the blood rather than to an actual increase of the amount of the phosphatase.

An exact study of the question was made possible by the work of O. Bodansky^{5, 6} on the relation of amino acids to phosphatase activity. He demonstrated that under optimal conditions of pH, amino acid, and magnesium ion concentrations, a measure of the reaction velocity of the hydrolysis of the substrate (sodium β -glycerophosphate) by bone phosphatase is proportional to the concentration of the enzyme present. It may be assumed, therefore, that the measure of the reaction velocity ($Q_{0.05}$) can be used to indicate the relative concentration of the phosphatase in the sera of persons with bone disease, especially since O. Bodansky⁷ showed also that the phosphatases of the bones and the blood probably are identical.

On the basis of this hypothesis, the experiments described herein were conducted on the blood sera of several patients with Paget's disease in an attempt to determine the relationship between the phosphatase activity and the quantity of the enzyme.

†The data in this paper represent a part of an investigation of the metabolism of bone supported by a grant from the Associate Committee on Medical Research of the National Research Council, Ottawa, Canada.

PROCEDURES

The methods described by A. Bodansky⁸ for the estimation of the inorganic phosphorus and phosphatase activity were used with the application of all the suggested correction factors for the deviation from Beer's law, the presence of trichloroacetic acid and glycerophosphoric acid, retardation of hydrolysis, and conversion to a standard time of one hour.

The extraction of the phosphatase was accomplished by treating the sera in the following four ways:

1. The serum was diluted and dialyzed in a collodion membrane for eighteen hours against distilled water. The dialysate, usually clouded with precipitated protein which dissolved on the addition of a few drops of dilute alkali, was diluted to a definite volume, and aliquot portions were used to estimate the reaction velocity.

2. The phosphatase and much of the protein were precipitated by the ether-alcohol method of Martland and Robison.⁹ The precipitate was filtered off, washed with an ether-alcohol-water (3:2:1) mixture, and dispersed in a definite volume of water containing a few drops of a dilute alkali solution. Aliquots were used as above for the reaction velocity.

While both the foregoing procedures removed inorganic matter, such as magnesium ions, phosphate ions, amino acids, and hydrolyzable organic phosphorus compounds, a large proportion of the serum proteins remained.

3. Considering the serum as a solution of phosphatase, the latter was fractionally precipitated by 95 per cent ethyl alcohol, according to the method of Albers and Albers.¹⁰

4. The first precipitation was carried out as in procedure No. 3, but the 50 per cent alcohol filtrate and washings were treated with either a triple volume of 2:1 ether-alcohol mixture or a double volume of 3:1 ether-alcohol mixture, and the precipitate was filtered off. Thus better yields of phosphatase with a degree of purity equal to that of the other methods were obtained with the added advantage that the second filtration was more rapid. This method proved to be the most satisfactory.

Aliquots of the solutions of phosphatase obtained by the procedures outlined were added to hydrolysis mixtures each composed of substrate, buffer, magnesium chloride solution, glycine solution, and dilute sodium hydroxide solution.¹¹ The hydrolysis mixtures and the enzyme solutions were brought to 25° C. before mixing, and the hydrolysis was carried out at 25° C. in a constant temperature water bath thermostatically controlled.

Portions of the hydrolysis mixtures were removed at intervals after the beginning of the reaction. In experiments where the serum had been treated as in the first two methods, the 1 ml. aliquots were added to 7 ml. of 10 per cent trichloroacetic acid solution. The resulting precipitate was filtered off (Whatman No. 44), and the phosphorus in 6 ml. of the filtrate was estimated by the method of A. Bodansky.⁸ When the serum was treated as in the third and fourth procedures, no appreciable precipitate formed; hence the 1 ml. aliquots were added to 5 ml. of the trichloroacetic acid solution and the phosphorus was estimated without filtration.

The tables devised by A. Bodansky⁸ were converted for the purpose of the present calculations by means of the factor 0.006, so that his data thus modified gave at once the concentration of phosphorus per milliliter of the hydrolysis solution. The results were corrected also for loss on filtration when necessary. The final results were plotted against the time of the hydrolysis and the $Q_{0.05}$, as recommended by O. Bodansky,¹² was calculated. This value was then related to the amount of serum used originally.

If the phosphatase precipitated from 5 ml. of serum is dissolved in 25 ml. of water and 2 ml. of this solution is used in the hydrolysis mixture, then $Q_{0.05} \times \frac{25}{2 \times 5}$ gives what may be regarded as a measure of the reaction velocity per milliliter of serum. This numerical value is proportional to the concentration of the phosphatase in the serum.

RESULTS

The results are expressed as the serum phosphatase activity in Bodansky units and the reaction velocity per milliliter of serum as shown in Fig. 1. The first three methods of extraction gave similar values and are not differentiated (curve A). The results obtained by the fourth method are represented by curve B. From this chart it is evident that as the serum phosphatase activity in Bodansky units increases, the measure of the reaction velocity, and hence the concentration of the phosphatase per milliliter of serum, increases in direct proportion.

The high serum phosphatase values found in these patients with Paget's disease are associated, therefore, with an increased concentration of the enzyme. The lower results obtained for the reaction velocities in curve A are attributed to losses of phosphatase in the third method of extraction and to inhibition by the serum proteins in the first two methods.

Not only did the concentrations of the phosphatase in the sera vary directly as the activity in Bodansky units in general, but each individual result was well above the normal range for both the activity in Bodansky units and the reaction velocity per milliliter of serum. This is exemplified by comparing the results depicted in Fig. 1 with those of a group of normal sera shown in Table I.

TABLE I
NORMAL SERA

SERUM PHOSPHATASE ACTIVITY (BODANSKY UNITS)	RELATIVE CONCENTRATION OF PHOSPHATASE	SERUM PHOSPHATASE ACTIVITY (BODANSKY UNITS)	RELATIVE CONCENTRATION OF PHOSPHATASE
2.23	0.00083	3.36	0.00137
2.50	0.00105	3.43	0.00124
2.54	0.00103	3.61	0.00142
3.03	0.00134	3.67	0.00140
3.15	0.00138	4.02	0.00146

From these observations it may be concluded that the sera of normal adults contain less phosphatase than the sera of patients with Paget's disease and that the increased serum phosphatase activity of the latter is not due to the

removal of an inhibitor normally present in the blood or to the addition of an activator of the enzyme. The elevation of the serum phosphatase activity in cases of Paget's disease appears to be due rather to an actual excess of the enzyme in the blood stream.

The data in Table I seem to be sufficiently consistent to indicate that the variations in the phosphatase activity of normal sera as well as those of Paget's disease are due to variations in the concentration of the enzyme.

Preliminary observations concerning patients with other diseases, such as jaundice and arthritis, also suggest that in those cases in which the serum phosphatase activity is elevated, the elevation is related to an increase of the enzyme in the blood.

Fig. 1.—Chart showing the direct proportionality between the serum phosphatase activity in Bodansky units and the concentration of the enzyme per milliliter of serum.

COMMENT

The observations described in this report are at variance with those of Thannhauser and associates.^{2, 3} If the increase of serum phosphatase activity in Paget's disease is due to the presence of an activator of the enzyme in the serum as they suggest, the increased concentrations of phosphatase, as indicated by elevated reaction velocities, which we found, would not occur. In order that the increased activity be caused by an activator, the latter would have to be similar in chemical and physical properties to the enzyme molecule itself so that it would be inseparable from it by the methods used for the purification of the enzyme.

If the increase of serum phosphatase activity is due to the removal of an inhibitor of the phosphatase which is normally present in the blood, the concentrations of the enzyme in the sera of normal persons and those with Paget's disease, as indicated by the reaction velocities, would present similar values.

This is not the case, for not only are the values generally higher for both the serum phosphatase activity and the relative concentration of the phosphatase in the patients with Paget's disease, but each individual determination is greater than even the highest normal value.

SUMMARY

Methods are outlined whereby the concentration of the serum phosphatase is expressed in relation to a measure of the reaction velocity of the substrate under specific conditions.

According to the evidence presented, the hyperphosphatasemia of patients with Paget's disease of bone is due to an actual increase of the concentration of the phosphatase in the serum as opposed to the view that it is related to the presence of an activator of the enzyme in the blood.

LABORATORY METHODS

GENERAL

THE PREPARATION OF ANTI-M, ANTI-N, ANTI-A, AND ANTI-B TESTING FLUIDS*

I. JEROME SILVERMAN, M.D., NEW YORK, N. Y.

TO PERFORM the simple blood-grouping test prior to transfusion, one must possess, as is well known, high titered anti-A and anti-B sera which are obtained ordinarily from particular group B and group A individuals, respectively. In a large hospital, where many blood-grouping tests are done daily, the supply of these two sera must always be adequate; or group A and group B individuals, whose sera are known to contain potent agglutinins, must always be at hand. However, group specific sera can also be prepared by immunizing rabbits with human blood and such immune anti-sera usually possess a high agglutinin titer, as shown by Hooker and Anderson,¹ Landsteiner² and von Dungern and Hirschfeld.³

Aside from the above blood group factors A and B, Landsteiner and Levine⁴⁻⁶ discovered other agglutinable properties in the human erythrocyte, which they called M, N, and P. (In this paper, factor P will not be discussed.) They found that every individual possessed either the factor M, N, or both M and N in addition to his blood group. To determine the presence of these agglutinogens M or N, immune rabbit serum was used since human agglutinins for M and N have not been found, aside from three rare exceptions.^{7a} An individual may be in the blood group O or A, or B or AB, and also belong to type M, N, or MN.

To produce these blood-group specific, immune anti-sera, the appropriate groups and types of human blood cells must be injected into rabbits. Various methods and techniques^{6, 7b-15} have been employed for the production of these immune anti-sera. Such sera have a wide practical application; namely, (1) checking doubtful reactions encountered in routine blood-grouping tests; (2) in medico-legal cases, the grouping of dried blood stains not too badly decomposed;^{16, 17} (3) exclusion of parentage;^{18, 19} (4) anthropologic studies;²⁰ (5) tracing the fate of the transfused red blood cell in patient's circulation.^{21, 22}

In this paper, I shall present my experiences with the preparation of anti-M, anti-N, anti-A, and anti-B immune rabbit sera, using Wiener's⁷ method of immunization. I do not claim that this procedure is superior to others.

PREPARATION OF ANTI-M AND ANTI-N TESTING FLUIDS

Anti-M.—In the preparation of anti-M serum, 8 rabbits were immunized with blood from an OM individual. OM cells were used to avoid the formation

*From the Laboratories of Pathology, Bellevue Hospital Out-Patient Department, New York City.

Received for publication, May 1, 1940.

of anti-A or anti-B agglutinins. Sterile precautions were taken throughout the procedures so that the final testing fluids, after ampouling, would be free of any bacteria. A total of 25 c.c. of OM blood were withdrawn into 5 c.c. of sterile 3.8 per cent sodium citrate, and this was immediately divided into six equal parts, each representing the total daily dose for the 8 rabbits. Before injection the blood sample was washed free of all plasma with physiologic saline and then suspended in about 20 c.c. of saline. Each rabbit was given intravenously 2 c.c. of this red blood cell suspension. The sixth daily injection was followed by a rest period of seven to ten days; this may be considered the first course. The first injection of each subsequent course was given subcutaneously to avoid anaphylaxis, but all other injections were given intravenously. No tests were made until end of third course, since Wiener^{7b},* found that only rarely were good sera obtained in a shorter time.

+++ complete agglutination.

- no agglutination.

Of the 8 rabbits injected with OM blood 7 remained alive, and from the marginal ear veins of these 7 rabbits about 5 c.c. of blood were withdrawn one week after the last injection of the third course. In addition to the anti-M agglutinins present, these 7 immune sera would also contain species agglutinins capable of agglutinating any human blood, and these so-called nonspecific antibodies must be removed by absorption with the proper human blood cells, in this case ON, AN, and BN bloods.* Accordingly, in the preliminary tests, each of the seven sera, after inactivation for one-half hour at 56° C., was diluted twenty times with saline, and to each now was added one-half volume of pooled, packed washed ON, AN, and BN blood cells, mixing thoroughly to insure as near a complete agglutination and absorption as possible. These tubes were left at room temperature for one-half hour, centrifuged, and the supernatant fluid tested against 2 per cent cell suspensions of OM, ON, and OMN blood. Since there was still a definite agglutination with ON cells, one-fourth volume of the pooled ON, AN, and BN cells was added to the supernatant fluid, and this second absorption removed completely the remainder of the species agglutinins. These seven fluids were then titrated against OM cells. Table I presents the reactions of the various sera in tests carried out in small test tubes at room temperature

*These known standard and controlled bloods are usually from doctors, nurses, or employees in the hospital and therefore are always available for absorption and testing purposes.

and read one hour after the set-up. The rabbits with a specific anti-M titer of 20 or more were then bled, their sera were inactivated at 56° C. for one-half hour, ampouled, and stored in an icebox. When anti-M testing fluid was needed, one of these ampoules was diluted twenty times with saline and absorbed with pooled N cells. This anti-M testing fluid was now ready for use.

Anti-N.—To prevent the formation of interfering agglutinins, anti-A and anti-B, ON blood was used for the injections, 8 rabbits being immunized by the technique already described. After the third course, 6 rabbits survived and their sera were tested, using pooled M cells for the absorptions. The same procedure was followed as outlined under "Anti-M," except that the sera were diluted fifteen times and the absorptions were carried out at 37° C. instead of room temperature. Three absorptions were necessary before all the species agglutinins were removed and the fluids were then titrated. In Table II it will be seen that the titers of the N agglutinins are lower than the titers of the M agglutinins (Table I), and only two of the anti-N sera were satisfactory for use.

TABLE II
PREPARATION OF ANTI-N SERA
PRELIMINARY TESTS

PREPARATION OF ANTI-A AND ANTI-B TESTING FLUIDS

Anti-A.—In the preparation of anti-A serum, 10 rabbits were immunized with AN blood in a fashion similar to that described under "Anti-M." Four rabbits survived and from the marginal ear veins of these 4 rabbits about 5 c.c. of blood were withdrawn one week after the last injection of the third course. As AN blood had been injected, each rabbit could be expected theoretically to produce specific agglutinins for N as well as for A. It was thought that should the rabbits fail to manufacture a serum rich in anti-A agglutinins perhaps they would produce a usable anti-N serum, especially since our anti-N yield from the ON immunization was not large.

Accordingly, in the preliminary tests, each of the four sera, after inactivation, was diluted fifteen times with saline and divided into two portions: one portion to determine the content of anti-A agglutinins and the other portion the content of anti-N. To the first portion of each inactivated and diluted rabbit's serum was added one-half volume of pooled, packed, washed OM, BN, OMN, and BMN cells,* mixing thoroughly to insure as near as complete agglutination and absorption as possible. These tubes were left at room temperature for one-

See footnote () page 1339.

half hour and centrifuged, and the supernatant fluid was tested against 2 per cent cell suspensions of OMN, ON, AMN, and BMN bloods. These tests showed that the first absorption in most cases was not complete, so a second absorption was performed, this time with one-fourth volume of the packed, pooled, and washed cells.

TABLE III
PREPARATION OF ANTI-A SERA
PRELIMINARY TESTS

IMMUNE, INACTIVATED SERUM DILUTED 15 TIMES AND ABSORBED WITH OM, DN, OMN, AND DMN CELLS		KNOWN BLOOD CELL SUSPENSIONS				INTERPRE- TATION
		OMN	ON	AMN	DMN	
Rabbit A4	1st absorption $\frac{1}{2}$ volume	±	±	±±	+	Very weak anti-A fluid
	2nd absorption $\frac{1}{4}$ volume	-	-	+	-	
Rabbit A5	1st absorption $\frac{1}{2}$ volume	-	+	+++	-	Strong anti-A fluid
	2nd absorption $\frac{1}{4}$ volume	-	-	+++	-	
Rabbit A6	1st absorption $\frac{1}{2}$ volume	+	±±	+++	+	Strong anti-A fluid
	2nd absorption $\frac{1}{4}$ volume	-	-	+++	-	
Rabbit A7	1st absorption $\frac{1}{2}$ volume	-	+	±±	-	Weak anti-A fluid
	2nd absorption $\frac{1}{4}$ volume	-	-	±±	-	

As can be seen in Table III, rabbits 4 and 7 produced a very poor anti-A serum, but rabbits 5 and 6 formed a strong anti-A serum. To determine the potency of the anti-A agglutinins in the sera from rabbits 5 and 6, each diluted and absorbed serum was titrated against suspensions of AMN and BMN bloods, as outlined in Table IV.

TABLE IV
TITRATION OF ANTI-A TESTING FLUID

TESTING FLUID	TESTED AGAINST	DILUTIONS OF TESTING FLUID								TITER
		1:1	1:10	1:20	1:40	1:80	1:160	1:320	1:640	
Rabbit 5	AMN	+++	+++	+++	+++	++	±	-	-	80
	BMN	-	-	-	-	-	-	-	-	
Rabbit 6	AMN	+++	+++	+++	+++	±±	++	++	±	320
	BMN	-	-	-	-	-	-	-	-	

To determine the content of anti-N agglutinins in the sera of the 4 rabbits, the second portion of diluted inactivated serum was used. To each was added a one-half volume of pooled, packed, washed OM, AM, and BM red blood cells. After standing at 37° C. for one-half hour, the tubes were centrifuged, the supernatant fluids were drawn off and tested against AM, BM, ON, and OMN cell suspensions. It was noticed that the fluids from the sera of rabbits 4 and 7 gave strong agglutination reactions with ON and OMN cells, but only a slight reaction with AM and BM cells; while the fluids prepared from sera of rabbits 5 and 6 reacted poorly. A second absorption was carried out on the supernatant fluids, 4 and 7, this time using one-fourth volume of packed and pooled M cells.

After the second absorption, these two fluids were retested and found to be satisfactory for titration against N cells. The titer of the anti-N agglutinins was found to be approximately 16 (compare with Table II).

It will be seen that of the 4 rabbits immunized with AN blood, 2 produced potent A antibodies and very little N antibodies, while the other 2 produced satisfactory anti-N agglutinins and only weak A antibodies. These 4 animals were bled to death, their sera were inactivated, ampouled, and stored in an icebox at 4° to 7° C. One cubic centimeter of this serum will yield about 15 c.c. of testing fluid after proper dilution and absorption. Before any testing fluid was ampouled, it was checked against several known control red blood cell suspensions. For example, anti-A test fluid was tested against OM, BN, AMN, and AN cells, and, of course, definite agglutination took place with the last two only, namely, AMN and AN. No preservative was added to the ampoules.

Anti-B.—Ten rabbits were given intravenous injections of BN red blood cell suspensions in a fashion similar to that described under "Anti-M."

At the end of the third course 4 rabbits remained alive and their four sera were examined in a manner analogous to that described for anti-A sera. One portion of the diluted anti-B sera was absorbed with pooled OM, OMN, AM, and AMN cells, thereby removing the species agglutinins and also any anti-A, anti-M, and anti-N agglutinins that might be present. The supernatant fluids, after absorption and centrifugation, were tested against known red blood cell suspensions of OMN, ON, AMN, and BMN blood. All four testing fluids reacted very weakly against BMN cells. The sera, therefore, from which these testing fluids were prepared were considered unsatisfactory for use. The unsuccessful result of this experiment conforms with the observation that it is far more difficult to prepare satisfactory anti-B immune sera than anti-A sera.¹⁰

As with the anti-A sera, the content of anti-N agglutinins was determined. The other portion of the inactivated and diluted anti-B serum was absorbed with OM, AM, and BM packed, pooled, and washed red blood cells. After absorption, the four fluids were tested against known AM, BM, ON, and OMN cell suspensions. The agglutination reactions against the N cells were weak and therefore the sera were not satisfactory for use.

DISCUSSION

In general, to prepare an immune anti-serum the following outline is advised:

1. Injection of specific antigen into sufficient number of rabbits.
2. Collection of small amount of serum from these animals for preliminary testing purposes.
3. Inactivation and dilution of these sera.
4. Absorption experiments until specific serum reacts with only its homologous antigen.
5. Titration.

Should the titer of anti-A, anti-B, or anti-M agglutinins reach 20 or higher, those rabbits are bled, their sera are inactivated and stored in an icebox as "Stock Serum." When, let us say, anti-M testing fluid is needed, one of these

ampoules of "anti-M Stock Serum" is diluted, absorbed, tested, and ampouled. With anti-N fluid, a titer of 10 or more is considered satisfactory.

As will be noted, a fairly large amount of blood is necessary both for the injections and especially for the absorptions. In a large hospital with its many steady employees and with its "Blood Bank," this seeming difficulty can be overcome.

An interesting observation is that in the present study we were far more successful in obtaining satisfactory anti-M sera than anti-N sera, which is contrary to the experience of most of the previous workers. This, as well as the variability in the response of the rabbits receiving AN blood (two forming good N antibodies but only weak anti-A; and the other two forming strong anti-A but practically no anti-N), serves to emphasize the importance of the individuality of the rabbit in relation to the results of the immunizations.

SUMMARY

1. Of 7 rabbits immunized with OM cells, 6 produced satisfactory anti-M serum.
2. Of 6 rabbits immunized with ON cells, 2 produced satisfactory anti-N serum.
3. Of 4 rabbits immunized with AN cells, 2 produced satisfactory anti-A serum and the other 2 produced satisfactory anti-N serum.
4. Of 4 rabbits immunized with BN cells, none produced a usable anti-serum.

I wish to take this opportunity to thank Dr. A. S. Wiener, Serologist to the Office of the Chief Medical Examiner of New York City, for his aid and many suggestions.

AN APPARATUS TO RECORD MOVEMENT OF THE EXTREMITIES*

RUDOLF V. GRIMMER, M.D., AND ORTHELLO R. LANGWORTHY, M.D.
BALTIMORE, Md.

THERE is a need for some simple method of recording which enables one to analyze quantitatively the ability to perform coordinated movements of the extremities and to show any abnormalities which may be present. It is only by such means that it will be possible to demonstrate the degree of functional disability which is present in patients with injury of the nervous system and to assay adequately the value of treatment.

The apparatus described here was devised primarily to study the value of drug therapy in patients with the Parkinsonian syndrome. These patients show great diminution in the range and speed of voluntary movements, together with a rhythmical tremor of the extremities. These may be influenced by certain drugs, as has been described repeatedly in the literature. It has, however, been impossible hitherto to obtain accurate comparative information concerning the relative value of these substances and the dose which gives the most satisfactory results. It is also apparent that a method satisfactory for this purpose could be adapted to a study of other abnormalities of muscular control, such as those seen in patients with athetosis or the cerebellar syndrome.

Doshay (1938) described a method of determining the "graphic rigidity index" in patients with the Parkinsonian syndrome. This is essentially a means of calculating the frequency with which groups of muscles can be contracted or relaxed and the rate at which the movements tire. The effect of atropine on these factors was studied. The apparatus used was not discussed in detail. The principles involved were similar to those which we have developed independently.

DESCRIPTION OF APPARATUS

The apparatus shown in Fig. 1 works as a pulley system, recording the efforts of a patient to move a weight in a vertical plane by contractions of the muscles at the elbow or wrist. During the wrist movement the forearm is held fixed against the arm of a chair. A lever, which is connected to the weight by means of a thread passed through a pulley, writes upon a kymograph. Time is registered at second intervals.

*From the Sub-Department of Neurology, the Johns Hopkins University and the Baltimore City Hospitals.

Received for publication, May 1, 1940.

While one hand is raising and lowering the weight, the other is at rest holding a balloon. This is inflated lightly and connected by means of rubber tubing to a tambour, the arm of which writes on the kymograph. Any tremor in the fingers of the resting hand is recorded by this method.

FIG. 1.

The patient is usually asked to raise and lower the weight a number of times as fast as possible, and then more slowly. The latter procedure is omitted if the maximum speed is greatly retarded. The result of maximal effort gives a good estimate of any rigidity which is present. The slow contraction, in particular, may show a superimposed tremor. However, in patients exhibiting the Parkinsonian syndrome the tremor is best portrayed in most cases by the balloon system from the resting hand. It is usually exacerbated during the time the patient is lifting the weight when his attention is withdrawn from this hand (Fig. 2) and when there is some emotional excitation.

Often the speed of contraction and relaxation in the individual with the Parkinsonian syndrome is greater when the weight which is lifted is increased from less than one pound to four or five pounds. Perhaps this is because the speed of the passive phase of the movement is increased and the interval between the active and passive phases is shortened.

This apparatus is not yet entirely satisfactory to record fast movements because of the rebound which is present in the apparatus. Consequently, it is difficult to demonstrate slight rigidity. It is hoped that this difficulty may be overcome by technical improvements.

DESCRIPTION OF RECORDS

For the purpose of illustration two records made from a patient with the Parkinsonian syndrome are shown in Figs. 2 and 3. Fig. 2 illustrates movements of the wrist, while Fig. 3 illustrates movements of the elbow. The upper tracing in both records indicates time in seconds, the middle one tremor in the resting hand and the lower one the actual muscle contraction. In the latter the upstroke indicates contraction and the downstroke relaxation.

Fig. 2.

Fig. 3.

In Fig. 2 the rhythmical tremor is present in the resting hand throughout the period of wrist movement. The tremors also are superimposed upon the tracing of muscle contraction, showing graphically the well-known cogwheel phenomenon. The amplitude of the wrist contractions tends to decrease as the act is repeated; it is less when the weight is increased.

Fig. 3 illustrates the movements of elbow flexion and extension. The tremor is well shown during the period of active flexion when the movement is performed slowly. The tremor in the resting hand is increased when the patient is pulling a weight of four pounds; then it undergoes exaggeration during the active flexor movements.

SUMMARY

A method of graphically recording voluntary movements and tremor in patients with the Parkinsonian syndrome is described. The apparatus is inexpensive and gives reliable records. It has been utilized to test the effect of drugs upon the rigidity and tremor which these patients exhibit.

A SIMPLE, CLEAN, CEDAR OIL BOTTLE*

S. STANLEY SCHNEIERSON, M.D., New York, N. Y.

CEDAR oil bottles, as a rule fitted with glass, wooden, or metal applicators that dip into a pool of oil, are not satisfactory because it is difficult to control the amount of oil desired and the direction of the oil on the slide. As a result, the bottle, the hands, the microscope, and its stage may become smeared with cedar oil.

FIG. 1.

The bottle described herein offsets these difficulties. It is very simple to make. We have found it to be clean and very convenient.

An ordinary stain dropper bottle is used. The tip is drawn out to a fine point in the pilot light of a Bunsen burner. The end is cut off, leaving a very small opening at the end of the dropper. It is important to have the opening exactly of the right caliber. If it is too large, the oil will drop by gravity and drip into the bottle. If it is too small, too much pressure will be required to get the proper flow.

The hollow inner part of the dropper is filled with oil by means of a Pasteur pipette, and the rubber teat is applied. The bottle is now ready for use.

When needed, the oil is merely dropped on any part of the slide just like a stain, and the amount to be applied is regulated by the degree of pressure on the rubber teat.

The dropper is refilled whenever necessary.

Since the dropper and sides of the bottle are ground and fitted, there is no evaporation and hardening of the oil.

HEMATOCRIT TUBE FILLING PIPETTE*

ARTHUR C. STIRLING, M.D., ROCHESTER, N. Y.

THE instruments and methods used in filling and in cleaning the fine bore hematocrit tubes of the Wintrobe type, now employed extensively for determining the blood sedimentation rate and erythrocyte volume in patients with arthritis, tuberculosis, or other infections, have been open to criticism on several points. We have described a new and simple device for the rapid cleaning and drying of such tubes.¹ Here we shall offer a solution to the vexing situation of constant breakage of the slender glass pipettes now employed to fill this type of hematocrit tube. This breakage is costly in time, and often in material, to the clinics where many such blood studies are made.

Fig. 1.—Hematocrit tube filling pipette. Refer to text for explanation of lettering.

The filling pipette here described (Fig. 1) is relatively nonbreakable under more than average usage. The slender stem (A), which extends to the full depth of the tube to eliminate bubble formation, is made from a stainless lumbar puncture needle by the removal of the beveled pointed tip. The thick ground glass shank of the glass bulb (B) is fashioned to fit snugly into the adapter of the needle, thus making a leak-proof yet easily detachable joint, such as is used with the common syringe. The bulb is made of glass to permit visualization of its contents, and holds about 2 cm. of blood. A rubber bulb (C) is added to this to facilitate the exchange of the oxalated blood via the filling pipette.

This device is quickly cleaned by simply detaching the parts and attaching them to the suction tubing used for cleaning the ordinary blood pipettes and the hematocrit tube itself.

THE DIAGNOSTIC VALUE OF THE COLLOIDAL CARBON FLOCCULATION TEST IN SPINAL FLUID*

PAUL B. SZANTO, M.D., SAMUEL BURACK, M.D., AND OSCAR KREISLER, M.D.
KANKAKEE, ILL.

IN A PREVIOUS paper¹ we investigated the diagnostic value of the Takata-Ara reaction of the cerebrospinal fluid in neurosyphilis. The purpose of this paper is to prove the value of the colloidal carbon flocculation test in spinal fluid in cases of neurosyphilis and to compare the results with the Lange test and the Takata-Ara reaction.

Benedek and von Thurzó² introduced the so-called Kolloid-Schultz Index test for the differential diagnosis of diseases of the central nervous system. Other workers³ were unable to confirm their results.

Looney,⁴ and later Looney and Stratton,⁵ prepared a stable colloidal suspension of carbon by electrolysis between two carbon electrodes. Their method, interpretation, and results were very similar to the Lange test. They stressed the fact that the test is at least as sensitive as the Lange test and that the suspension is more stable.

Schube and Harms⁶ modified and simplified Looney's method. These workers, and later Deadman, Elliott, and Smith⁷ showed that in cases of positive Wassermann reaction in spinal fluid the colloidal carbon flocculation test in about 90 to 95 per cent of the cases was also positive. Various workers confirmed these results, especially Selesnick,⁸ who examined 478 cases. Of these, there were 55 cases of neurosyphilis, and in every case of a positive spinal Wassermann he found a positive colloidal carbon flocculation test. In over 400 cases where the spinal fluid was negative for syphilis there were only eight "false positive" reactions. In these "false positive" cases he found rapidly growing bacteria in the spinal fluid which he stated were the causes for the positive reactions.

METHOD

We used the method of Schube and Harms⁶ with the exception that we found that four tubes gave sufficiently accurate results. Into each of four Wassermann tubes are placed 1 c.c. of distilled water. One cubic centimeter of spinal fluid is placed in the first tube which is well agitated, and 1 c.c. of the mixture is transferred to the second tube, etc. One cubic centimeter of fluid is discarded from the fourth tube. In a fifth tube one cubic centimeter of distilled water is used as a control. Into each tube is now placed 0.1 c.c. of a 0.1 per cent oxalic acid solution and then 0.4 c.c. of a 1 per cent colloidal carbon suspension. The resulting mixture is well agitated. The colloidal carbon solu-

*From the Kankakee State Hospital, Kankakee, Dr. G. W. Morrow, Managing Officer.
Received for publication, May 6, 1940.

tion we used was prepared as follows. One cubic centimeter of Carter's Black India Ink No. 358 is diluted with distilled water up to 100 c.c., and this is the reagent used.

Interpretation.—The flocculation test is considered positive when there is complete precipitation and the supernatant fluid is absolutely clear. If these conditions occur in any one of the four tubes, the reaction is considered positive. The results are read after twelve hours.

MATERIAL AND RESULTS

We examined 268 patients of whom there were 156 with general paresis. Of the 112 nonparetic patients 46 had dementia praecox, 39 had chronic alcoholism, 14 had cerebral arteriosclerosis, 6 had idiopathic epilepsy, and 7 were mentally deficient.

In every nonsyphilitic case the test was negative. In 141 cases of positive spinal Wassermann the colloidal carbon flocculation test was also positive. In the other 15 cases of positive Wassermann the colloidal carbon flocculation test was negative, or, in other words, the test was positive in 90.4 per cent of the cases of general paresis.

COMPARISON WITH OTHER TESTS

1. Gold sol test. In 44 cases with typical first zone curve (paretic curve) the colloidal carbon flocculation test was always positive. In 51 cases with a middle zone curve, the colloidal carbon flocculation test was positive in 49 cases. In 10 cases with an end zone curve, the colloidal carbon flocculation test was positive in 8 cases. In 47 treated cases with a negative Lange, but positive Wassermann, the colloidal carbon flocculation test was positive in 36 cases.

2. Takata-Ara test. We compared the results in 134 cases of general paresis. In 104 cases where the Takata-Ara test was positive, the colloidal carbon flocculation test was positive in 102 cases. In 31 cases of negative Takata-Ara reaction the colloidal carbon flocculation test was positive in 25 cases.

COMMENT

The colloidal carbon flocculation test appears to be more sensitive than the Lange and Takata-Ara tests. It is positive in about 90 per cent of cases where the spinal Wassermann is positive. The test continues to be positive in treated cases of general paresis, where the Ross-Jones test, cell count and Lange test are already normal. Our cases gave no "false positive" results. Because of the simplicity of the test, it can be used where ordinary laboratory facilities are not available.

SUMMARY

The colloidal carbon flocculation test was positive in 90.4 per cent of cases of general paresis with a positive spinal Wassermann.

The test is more sensitive than the gold sol and Takata-Ara tests.

100 EAST JEFFERY STREET

AN AUTOMATIC BLOOD PRESSURE RECORDING APPARATUS*

HARRY WEISS, C.E., M.D., PH.D., NEW YORK, N. Y.

THERE is at present no device or principle that permits the continuous, simultaneous, and automatic recording of the systolic and diastolic pressures, the pulse pressure, and the pulse rate. Such a device would open a wide field of clinical and experimental investigation. It also has obvious practical values.

This communication describes such a basic principle and gives the description of an instrument that will furnish these data. The apparatus is designed to permit readings at fixed intervals over predetermined periods and under varying conditions, such as sleep, rest, and moderate activity. The results, furthermore, are entirely comparable with the readings obtained by the ordinary auscultatory method.

The principle is that of a fluctuating base line resembling a sine curve, which is projected onto a calibrated film or paper by means of a moving oscilloscope, galvanometer, or similar device. This fluctuating base line is produced by, and corresponds to, the changing pressures in a blood pressure cuff. The sensitive element within the oscilloscope (crystal, or a conductor in a magnetic field) or the galvanometer (conducting string) is then independently activated by sounds picked up microphonically at the antecubital space. This results in a deflection from the base line by each sound produced. These sounds are produced with each pulse beat in the pressure range between systole and diastole, and the points at which they appear or disappear represent the systolic and diastolic pressures. The pressure range between these two records the pulse pressure. The pulse rate is obtained by imposing a timer element on the record.

The apparatus is shown in Figs. 1 to 4. Fig. 5 is a representation of the graph obtained. The apparatus consists of a flat metal base plate (1) to which is rigidly attached an inverted U-shaped holder (2). The points of attachment

*From the Second Medical Service, Mount Sinai Hospital, New York.
Received for publication, May 10, 1940.

are at (3) and (4). At the midpoint of the horizontal member or roof of this inverted U-shaped holder, there is a small socket (8). On the lower surface of this socket there is a smooth depression (9) to receive a pivot. Opposite this socket and rigidly attached to the base plate midway between the two legs of the inverted U there is another socket (10) which also contains a similar smooth depression (11) and into which another pivot fits.

Fig. 1.

An oscillometer, otherwise known as an oscilloscope, is suspended between these two pivotal points so that it can rotate freely both clockwise and counter-clockwise. There are two pivots fixed to the oscillometer, one at its lower end (13) and the other at its upper end (14). These fit into the corresponding sockets (9 and 11).

The oscilloscope* shown in the drawings consists of a hermetically sealed chamber (15) in which there is a crystal bimorph element (16) fixed to its casing at the lower end, the upper end being free. To this free end a small mirror (17) is attached by means of a filament (18). This end is thus free to vibrate torsionally and independently, and with it the attached mirror. There are two contacts (19 a and b) leading from the bimorph element within the oscilloscope to which conducting wires are attached so that a current may be induced to flow through the element, causing it and the attached mirror to vibrate as described. The unit is filled with oil which serves as a damping agent and also protects the crystal against physical shocks. A window (20) in the head of the oscilloscope, sealed by a plano-convex lens affords access to the mirror and enables the light from the mirror to be brought to a focus without any additional optical parts.

A beam of light reflected from the mirror through the window moves with the movement of the mirror and is recorded on a recording camera. The source of light can be independent of the apparatus shown, or it may be fixed as

*The oscilloscope described is a modification of the Brush Piezo-Electric Oscilloscope Unit.

Fig. 2.

FIG. 3.

Fig. 4.

desired, either to the base plate, to the inverted U member, to the oscilloscope or to the upper pivot of the oscilloscope extended through the top of the inverted U. Its position depends on the desired placement of the camera which is controlled by factors of convenience and compactness.

The oscilloscope described in this communication and on the drawings is a crystal bimorph unit, but any other oscillometer, such as those commonly used in electrical practice which employ a conductor in a magnetic field, can serve the same purpose.

The current activating the oscilloscope element and mirror to move within its case comes from a microphone (21) which is appropriately electrified and is designed to be applied to the antecubital space of the arm below a blood pressure cuff. The current from this microphone, induced by the sound produced at the antecubital space, then passes through an appropriate apparatus (induction coil, resistance, etc.) to the binding posts of the oscilloscope, and as a sound is produced at the microphone the mirror within the oscilloscope twists and the beam of light reflected into the camera from the mirror records this movement.

Rigidly attached to the oscilloscope at (25) is a section of a gear (26). This gear meshes with a second gear (27), which is rigidly attached to the pivotal shaft (28) of an anaeroid (30) at point (29). The anaeroid is fixed through a saddle (31) to the base plate. The air entrance and outlet of the anaeroid is at (33), and to this is attached a tube (34) leading through a T to an air pump (36) or metal bellows. These can be adjusted for desired pressure ranges.

The other leg of the T (35) is attached through a tube (39) to a three-way valve (40). Through this three-way valve two other connections are made, one through a tube (41) to a hand bulb such as is used in the ordinary blood pressure apparatus and which incorporates a by-pass to the outside air, the other through a tube (42) to a blood pressure cuff which encircles the arm just above the point of application or attachment of the microphone at the antecubital space. The hand bulb is used for purposes of adjustment. During the automatic operation of the instrument, it is closed off at the three-way valve (40) and the arm cuff is open to the pump.

OPERATION

The apparatus operates as follows: The motor, geared down to a slow speed, operates the eccentric to which the piston shaft (38) is attached. This causes a slow reciprocating action of the piston head (37) in the pump cylinder (36) and results in the reciprocal movement of air into and out of the anaeroid (30) and the arm cuff. With this rising and falling of the air pressure there is a corresponding clockwise and counter-clockwise movement of the pivotal shaft (29) of the anaeroid (30). As this takes place the gear (27), rigidly attached to this pivotal shaft, moves likewise. The gear (27) meshes with the oscilloscope gear segment (26), causing it to rotate backward and forward. This gear segment (26), being rigidly attached to the oscilloscope, causes that unit to rotate both counterclockwise and clockwise.

A beam of light is reflected from the oscilloscope mirror (17) onto the moving sensitized film or paper of the camera, and a line is obtained resembling a sine curve which is smooth and represents the base line upon which the blood pressure readings are to be recorded. This base line is calibrated to run between any desired blood pressure levels by means of the displacement permitted the pump cylinder head within the pump casing. The upper limit of its excursion is adjusted and fixed through the motor-driven eccentric, the lower limit through the hand bulb. It is, of course, preferable that this lower limit be at a pressure of zero millimeters of mercury for the convenience and comfort of the patient.

Fig. 5.

This smooth basic curve is shown in Fig. 5a. If it is desired to take readings at a higher blood pressure level and over a larger range, the eccentricity of the driving motor is increased and the basic curve will be as shown in Fig. 5b.

As the apparatus is being alternately inflated and deflated by the pump and the basic line is being drawn, the pressure in the arm cuff rises and falls in corresponding fashion. As the pressure rises from zero to the diastolic pressure, no sound is produced in the antecubital space up to the point of diastole where the sound appears because the artery is now being compressed. This sound is detected by the microphone (21) fixed over the artery in this space. As the pressure continues to rise, these sounds persist with each heart beat until the pressure rises to the point of systole when the sounds disappear because the artery is now completely occluded. As the pressure falls the same events take place, except that the sequence is now reversed.

The sounds produced in the antecubital space and picked up by the microphone (21) give rise to electrical impulses which are transmitted to the crystal (16) (or field loop) of the oscilloscope (12), causing it to distort or twist and simultaneously to twist the attached mirror (17) through the suspension (18). This distortion or twist causes a deviation from the smooth base line described and produces irregularities in this line which represent at their beginning and ending the points of systole and diastole. Such a curve is represented in Fig. 5c.

Pulse rates are obtained by means of a timer recording on the film.

The apparatus is automatically controlled by means of a clock mechanism to take records at various predetermined intervals and over any desired periods. The automatic control of the instrument, which is not new and therefore not shown, consists of a timing device which regulates the stopping and starting at fixed points and permits the instrument to run for fixed periods. It simultaneously switches on and off the pump motor, the camera motor, the source of light, the camera shutter, the timer, and the microphone. The "make and break" is planned to take place at the lowest pressure phase so that there may be no pressure on the arm during the intervals when readings are not being made.

SUMMARY

A blood pressure recording device is described which functions automatically and which can record both systolic and diastolic pressure readings. These readings can be taken in the absence of a physician or operator, permitting blood pressure recording during sleep, rest, and various phases of activity. The records obtained are entirely comparable with the readings obtained by the ordinary auscultatory method. The instrument also records the pulse pressure and the pulse rate.

The instrument functions as a complete unit for the purpose described. It is intended to employ it further as part of a cardiodynamometer to measure relative cardiac efficiency.

Addendum.—During the development of this instrument other devices were designed which employ the same basic principle, that of a sound-sensitive element moving in synchrony with an induced pressure. One such design utilizes a galvanometric string oscillating in a split magnetic field. Another employs a fixed galvanometer string and an oscillating camera. A third employs a mirror that moves torsionally with pressure change and reflects the shadow of a fixed galvanometer string into a fixed camera.

A MANUALLY OPERATED ERGOMETER*

GEORGE R. MENERLY, M.D., AND NOLAN L. KALTREIDER, M.D.
ROCHESTER, N. Y.

FOR a number of years it has been our custom to use a bicycle ergometer of special design in certain experiments in which the respiratory exchange was measured during muscular exercise. With certain patients difficulties were encountered, which led to the use of an ergometer which could be operated by hand while the patient was comfortably seated in a chair. In this ergometer, the work was measured by recording the output of an electrical generator. The principle has been employed by Kelso and Hellebrandt.¹

The construction of the ergometer is evident from Fig. 1. The sprocket tooth ratios were selected to drive the motor at approximately its rated speed with convenient cranking rates. The electrical circuit is diagrammed in Fig. 2. The motor generator acts as a brake, and the patient overcomes the resistances, both mechanical and electrical, and produces electrical power which is dissipated by the load resistances as heat. An easily readable voltmeter is placed before the patient, who maintains his output constant by watching it.

The method of calibration is a familiar one in electrical engineering practice:

1. Output of the subject = input to the ergometer.

2. Input to the ergometer = armature generated power plus power losses.

$$3. P = P_a + P_s \quad (1)$$

where P = output of subject in watts
 P_a = armature generated power
 P_s = power losses

$$4. P_a = I_a \times E_g \quad (2)$$

where I_a = armature current
 E_g = generated voltage

$$5. I_a = \frac{E_t}{R_l} \quad (3)$$

where E_t = terminal voltage
 R_l = resistance of load resistance

$$6. E_g = E_t + B_d + (I_a \times R_a) \quad (4)$$

where B_d = brush drop
 R_a = resistance of armature

$$7. P_a = \frac{E_t^2}{R_l} + \frac{E_t \times B_d}{R_l} + \frac{E_t^2 R_a}{R_l^2} \quad (5)$$

by substituting (3) and (4) in (2).

8. The ergometer was cranked by hand with selected field currents at arbitrarily chosen terminal voltages, and values for P_a at these values for E_t were calculated from (5).

*From the Department of Medicine, University of Rochester, School of Medicine and Dentistry, and the Medical Clinics of the Strong Memorial and Rochester Municipal Hospitals, Rochester.

Received for publication, May 16, 1940.

Fig. 1.—Construction of ergometer. The generator is a $\frac{1}{12}$ th horse power D.C. shunt wound motor.

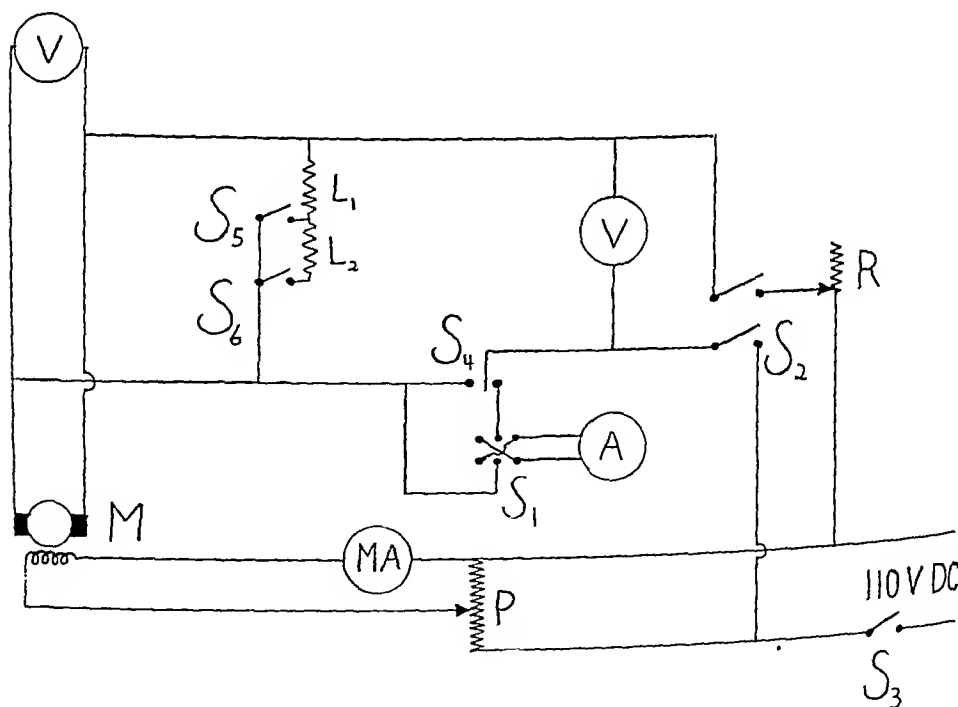

Fig. 2.—Electrical circuit. The field of the motor generator (M) is separately excited. The potentiometer (P) adjusts the field current to any desired value measured by the milliammeter (MA). The armature generated power is dissipated by the load resistances (L_1 and L_2) as heat. The voltmeters (V) are one for the patient and one for the observer. Power may be supplied to the armature for calibration purposes by the switch (S_2) and controlled by the resistance (R). The ammeter (A) and the ammeter reversing switch (S_1) are for the purposes of calibration also and may be thrown in and out of the circuit by a switch (S_1). A main power switch (S_3) is provided.

9. Power losses are of two sorts: "copper losses" and "stray power losses." When the ergometer was run motor action, the electrical input overcame these losses:

$$(E_a \times I_a) = P_c + P_s \quad (6)$$

where E_a = input voltage (effective armature voltage)

I_a = input amperage (armature current)

$E_a \times I_a$ = input power

P_c = copper losses

P_s = stray power losses

$$10. \text{Hence } E_a \times I_a = P_s + I_a^2 R_a + B_d I_a \quad (7)$$

where $I_a^2 R_a$ = armature copper loss

$B_d I_a$ = brush drop loss

$$11. \text{Now } E_a = E_t - B_d \quad (8)$$

$$12. \text{Hence } P_s = (E_t - B_d) I_a - I_a^2 R_a - B_d I_a \quad (9)$$

from (7) and (8)

where $P_c = I_a^2 R_a + B_d I_a$

13. The ergometer was run motor action and stray power losses for various r.p.m. were calculated from observed load terminal voltages (E_l) and armature current for several empirically chosen values of field current by (9).

14. The ergometer was operated with only a voltmeter in the armature circuit and no load terminal voltages for the r.p.m. used above were observed at the same field currents used in 13.

15. The voltage at the terminals at load is related to no load terminal voltages by the following:

$$E_l = E_{nl} - B_d - I_a R_a \quad (10)$$

where E_l = load terminal voltages

E_{nl} = no load terminal voltages

16. Substituting (3) in (10)

$$E_l = \frac{E_{nl} - B_d}{1 + R_a/R_l} \quad (11)$$

17. For any value of E_l a value of E_{nl} can be found and hence an r.p.m. for given field currents (steps 16 and 14).

18. By adding a value for armature generated power (from step 7) to the stray power loss corresponding to that terminal voltage (from 17), a total power is found which represents the input of the patient to the ergometer (1).

The power in watts was converted to kilogram meters per minute; from this a graph was prepared showing kilogram meters per minute versus load terminal voltage for the field currents and load resistances used (Fig. 3). The higher the field current, the lower the cranking rate is for the same amount of work. In use, the cranking rate and desired working rate are translated into load terminal voltage and field current. The operator brings the ergometer to speed and indicates to the patient the desired voltage on the voltmeter before him. He is instructed to take over the cranking at a given command. An observer records the terminal voltage every thirty seconds during the exercise period, and maintains the field current constant manually when necessary. At the end of the exercise period the patient releases the cranks and allows them to spin freely.

Table I shows four experiments comparing a normal person and a patient with cardiac disease on the hand and bicycle ergometers. Strict comparison is not possible because the amount of work is different, but two facts are apparent: The mechanical efficiency is greater with the bicycle ergometer, and exercise with the arms appears to augment the ventilation more than exercise with the legs.

TABLE I

COMPARISON OF TWO PATIENTS ON THE HAND AND ON THE BICYCLE ERGOMETER

SUBJECT	N.K. (NORMAL)		H.K. (CARDIAC)	
	Hand	Bicycle	Hand	Bicycle
Ergometer				
Time, minutes	3	3	3	5
Work, kilogram meters/minute	250	432	260	315
Work, calories	1.758	3.036	1.827	3.695
Excess heat production, calories	10.454	16.907	14.974	24.776
Net efficiency per cent	16.82	17.96	12.20	14.91
Ventilation/minute exercise	17.04	19.13	26.1	26.0
Total oxygen debt	0.520	1.127	1.688	2.356

DISCUSSION

No method of calibrating a motor is free from criticism. The method reviewed here is standard engineering practice and is fully discussed in textbooks on this subject. The generator used in the apparatus of Kelso and Hellebrandt was an automobile starting motor. It had advantages over the one

Fig. 3.—Calibration curve. At a selected value of work, any one of a number of values may be chosen, depending on the cranking rate suitable for the patient. The lower the field current, the greater the cranking rate for the same amount of work.

used in this ergometer. A family of curves was obtained in the calibration rather than a single curve for all values of field current as was the case with their machine. The advantage of the single curve is that the field current may be varied to change the cranking rate, yet the working rate will not vary as long as the terminal voltage is held at the same value.

It is advantageous to incorporate the motor power circuit permanently in the apparatus, as this makes it possible to check the calibration at any time in a few minutes.

SUMMARY

Certain objections to the use of the bicycle were overcome by construction of a manually operated ergometer. The motor-generator braking principle was used. The method of calibrating this apparatus is briefly reviewed. Comparison with the bicycle ergometer showed that the mechanical efficiency of the arms is less than that of the legs, and that exercise with the arms augments ventilation more than exercise with the legs.

A TECHNIQUE FOR THE ARTIFICIAL INSEMINATION OF THE WHITE RAT*

RICHARD J. BLANDAU, PH.D., AND EDWIN S. JORDAN, A.B.
PROVIDENCE, R. I.

ARTIFICIAL insemination of laboratory mammals is of increasing importance in studies of the physiology of ova and spermatozoa. In the rabbit,^{1, 2} guinea pig,³ and dog,^{4, 5} artificial insemination may be successfully carried out by merely depositing a sperm suspension in the vagina. In the rat, on the other hand, numerous attempts to impregnate females in heat by depositing sperm suspensions in the vagina alone resulted in complete failures.

Tochem⁶ artificially inseminated rats by operating and injecting sperm suspensions directly through the uterine walls. Fragmentary reports relating to the artificial insemination of female rats and mice⁷ may be found in the literature, no one of them completely satisfactory in the life of recent developments.

The technique here described has been used successfully in the artificial insemination of over 500 female rats during a study of the fertilizing capacity of old ova.

As a basis for the proper time for insemination we have depended upon the behavioral responses or sexual receptivity as elicited in the female rat during heat.

When the region of the iliac crest of a female rat in heat is manually stroked, she assumes the characteristic posture of lordosis. This posture is characterized by an extension of the limbs, arching of the back and a raising of the pudendal area and tail. The onset of heat can be accurately determined by this response. The relationship between the onset of heat and ovulation is sufficiently definite that the latter may be said to occur approximately ten hours after the beginning of heat.⁸⁻¹¹

*From the Arnold Biological Laboratory, Brown University, Providence.

This investigation was supported by a grant from the Committee for Research in Problems of Sex, National Research Council.

Received for publication, May 18, 1940.

Since the animals which were to be inseminated were not allowed to copulate, the cervix uteri of each animal was stimulated during heat by a strong faradic current, according to the technique of Greep and Hisaw,¹² and Astwood.¹³

When a female rat is to be inseminated, a normal adult male is killed by grasping it by the tail and striking its entire body sharply against a solid object. Any other method for killing usually results in struggling, urination, and ejaculation, with the resultant loss of sperm. This loss can be entirely avoided after a few trials in the proper method for killing the male.

The male is immediately opened by a ventral incision. The bladder is retracted posteriorly by a Kelly clamp, and the cauda epididymides and vasa deferentia are removed with a fine pair of scissors. Fat tissue adhering to the cauda epididymides is dissected away.

Contrary to the usual method of macerating the epididymides and vasa deferentia in Loeke's solution, and subsequently drawing off the sperm suspension from the debris, a technique has been devised by which a pure sperm suspension is obtained. This is of importance since the suspension must be drawn into a relatively fine hypodermic needle for insemination. It also eliminates the possibility of contamination by the presence of gross amounts of cellular debris.

The cauda epididymis is held between the fingers, and the cut end of the vas deferens is put into a small dish which is to receive the sperm. Using a medium point forceps, the epididymis is now massaged with increasing pressure toward the vas deferens. If this is done properly, ribbons of spermatozoa will be seen to exude from the distal end of the vas deferens. When sufficient spermatozoa have been removed from the epididymis, the massaging is continued along the vas deferens so as to force the remaining spermatozoa from it. Both epididymides are treated in a similar manner, the result being a viscid mass of densely packed spermatozoa. To this sperm mass is added 0.2 c.c. of Loeke's solution, which has been kept at 12° C. in a refrigerator. The suspension is then drawn into a tuberculin syringe to which has been attached a No. 21 hypodermic needle. The point of the needle has been ground down so as to present a blunt, smooth surface which will not injure the cervical canals. Care should be taken to have a thick, viscid suspension of spermatozoa for each insemination.

Just prior to insemination the female is lightly anesthetized with ether. During insemination the anesthetized animal is held by the base of the tail, with its back resting on the edge of an ordinary laboratory ring stand. An ear speculum of 5 mm. diameter at its smallest bore is placed deep into the vagina. By the use of a physician's reflecting mirror, the cervix may be illuminated and observed directly. The hypodermic needle is inserted into each cervical canal, and one-half of the sperm suspension is injected into each horn.

In order to be certain that the sperm suspension will remain in the uterine horns after insemination and not flow back into the vagina, especially if animals are inseminated near or after the end of heat, a plug is made in the following manner: A seminal vesicle with its associated coagulating gland is cut near its base and quickly brought to a flat, glass surface. The secretion is expressed from the seminal vesicle by stroking the gland with a probe. The secretion of the

coagulating gland must be expressed separately from that of the seminal vesicle, because if mixing of the two secretions occurs, coagulation immediately takes place. After the female has been inseminated, and while she is still under anesthesia, a small cotton plug is dipped, first, into the secretion of the seminal vesicle, then into the secretion of the coagulating gland. The plug is immediately transferred to the vagina through an ear speculum and pressed against the cervix. If done properly, the plug will simulate the vaginal plug formed during normal copulation and will aid in the retention of the spermatozoa in the uterine horns.

The percentage of impregnations from animals artificially inseminated during heat by this technique is as high as in animals which have been allowed to copulate normally. By use of this method, inseminations may be made at any time of the reproductive cycle when the female would otherwise not copulate.

A STUDY OF THE BLOOD CELLS OF NORMAL GUINEA PIGS*

E. S. KING, M.D., F.A.C.P., AND MARGARET LUCAS, A.B., M.T.
WAKE FOREST, N. C.

PREPARATORY to an experiment in which we were very much interested, it became necessary to know the normal blood cell picture of guinea pigs. This information was necessary before we could recognize any abnormal change that might occur in the blood during the course of the experiment. We wrote to two or three publishing companies for books or references describing the anatomy and physiology of these animals, but without any success. We were, of course, interested primarily in the cellular constituency of the blood. In the search for such information we found one author¹ who names with percentages the normal cellular elements of the blood of these animals, along with several other laboratory animals. Not being content, we set out to make daily blood examinations of a group of normal guinea pigs in order to establish an average normal. Our results are as shown below.

PROCEDURE

We obtained² nine normal full-grown guinea pigs (ages unknown). They were held under quarantine for several days to rule out the presence of any disease and to accustom them to new surroundings. They were kept in clean cages in a well-lighted and well-ventilated room, and fed a full-balanced diet. A part of the diet consisted Purina complete rabbit chow. This was reinforced with lettuce, cabbage, carrots, etc.

Examination of the blood was made daily for eighteen to twenty-one days. Blood was collected from the margin of the ears by making a small skin incision which allowed free bleeding. Each examination consisted of a red and white blood cell count and a differential. We did not do any hemoglobin determinations. Counts and smears were done in the usual way. Calculations which were used to arrive at an average normal were as follows: An average of the eighteen to twenty-one daily examinations for each animal was taken. Then from these averages the average for the nine guinea pigs was obtained.

RESULTS

Our study revealed that there was a rather wide variation in the total white and differential counts in some animals from day to day. However, there were not a great many counts that were conspicuously far away from the predominating range. The daily count of the red corpuscles, on the other hand, showed little variation and stayed within a rather narrow range. As to the individual white cells, there was moderate variation from day to day, and in a few instances a marked variation from the previous day. In these instances of marked

*From the Department of Bacteriology, School of Medicine, Wake Forest College.
Received for publication, May 24, 1940.

variation, the succeeding counts did not show a return to the previous count, but continued to fluctuate. We noted nothing of any unusual size or shape of the cells.

Our conclusions were that the neutrophiles showed a range of from zero to 76 per cent, with an average of 31.1 per cent; the lymphocytes a range of from 20 to 97 per cent, with an average of 63.1 per cent; the monocytes ranged from zero to 10 per cent, with an average of 1.8 per cent; the eosinophiles ranged from zero to 14 per cent, with an average of 3.5 per cent; and the basophiles ranged from zero to 2 per cent, with an average of 0.19 per cent. The results of this study are summarized in Table I.

TABLE I*

ANIMAL NUMBER	R.B.C.	W.B.C.	NEUTRO- PHILES (PER CENT)	LYMPHO- CYTES (PER CENT)	MONO- CYTES (RANGE AND PER CENT)	EOSINO- PHILES (RANGE AND PER CENT)	BASO- PHILES (RANGE AND PER CENT)

9	5,079,231	20,672	31.6	60.7	0 to 5 1.6	0 to 12 6.0	0 to 1 0.04
Average†	5,063,970	17,365	31.1	63.1	1.8%	3.5%	0.19%

*These figures are averages of the twenty-one daily counts of each animal

†The bottom horizontal line of figures is the average count of the nine animals.

SUMMARY

1. Blood examinations were made daily of nine healthy guinea pigs for from eighteen to twenty-one days.
2. The animals were fed a full-balanced diet during the period of investigation.
3. Rather wide variation in the white blood cell count was noted from day to day. Moderate to marked variation was seen in the different types of white blood cells. The red blood cell count remained rather fixed within a narrow range.
4. Normal averages found were: red blood cells 5,063,970, white blood cells 17,365, neutrophiles 31.1 per cent, lymphocytes 63.1 per cent, monocytes 1.8 per cent, eosinophiles 3.5 per cent, and basophiles 0.19 per cent.

CHEMICAL

PROTHROMBIN ESTIMATION USING RUSSELL VIPER VENOM*

I. SIMPLE MODIFICATION OF QUICK'S METHOD

ROBERT C. PAGE, M.D., NEW YORK, N. Y., AND HOLLIS K. RUSSELL, M.D.
WHITE PLAINS, N. Y.

THE determination of the prothrombin coagulation time in clinical practice is assuming increasing importance as knowledge of vitamin K deficiencies accumulates. The prothrombin estimation tests, in order to be of greatest service to the clinician, must be easy to perform, and their interpretation must be simple.

The tests for determining prothrombin time in general use (Quick, 1938; Smith and others, 1939; Kato and Poncher, 1940) employ thromboplastin prepared from tissue extract. Such extracts vary in potency and readily deteriorate, so that it is necessary frequently to check them against extracts of known potency. These factors lessen the efficiency and accuracy of the test and make it more difficult for the smaller clinical pathologic laboratories to use it to the fullest advantage.

In order to simplify the prothrombin estimation test, methods that do not employ tissue extracts have been developed, such as the modified Howell's method of prothrombin (Cheney), in which oxalated plasma is added to four tubes containing increasing amounts of calcium chloride (0.4 to 2 mg.), the shortest time of clot formation being taken as the coagulation time of the plasma.

A simple modification of Quick's method has been reported by Fullerton, who used Russell viper venom instead of tissue extract. Russell viper venom possesses the following advantages: (1) it is constant in potency, (2) it is in a clear solution, and (3) it permits more easily the observation of the end point of the formation of a fibrin web during the performance of the test than does the use of a milky tissue extract.

The following study was carried out because of these apparent advantages and in order to compare the prothrombin coagulation times on the blood of the same patients using the two methods.

METHODS

Blood of normal individuals, of patients in a general hospital population, and of patients attending outpatient clinics was used.

Four and a half cubic centimeters of venous blood were mixed with 10 mg. of potassium oxalate, centrifuged, and the oxalated plasma was obtained.

*From the Department of Pathology, St. Agnes Hospital, White Plains.
Received for publication, October 30, 1940.

Two tests were performed on each sample of plasma:

(1) Quick's (1938) method of prothrombin coagulation:

0.1 c.c. of oxalated plasma

0.1 c.c. of thromboplastin solution (rabbit brain)*

0.1 c.c. of calcium chloride solution

The time as determined with a stop watch from the addition of the calcium to the formation of a fibrin web was considered to be the prothrombin coagulation time.

Comparison of Prothrombin Coagulation Time between Quick's Method and Modified Quick's Method Using Russell's Viper Venom

□ QUICK'S METHOD ■ MODIFIED QUICK'S METHOD

N-Denotes Essentially Healthy Individuals

Fig. 1.—Prothrombin estimation using Russell viper venom and tissue extract.

(2) Modified Quick's method with Russell viper venom:

0.2 c.c. of oxalated plasma

0.2 c.c. of Russell viper venom (1:10,000) solution†

0.2 c.c. of calcium chloride solution (1.11 per cent calcium chloride)

The time from addition of the calcium chloride to the formation of a fibrin web was taken as the prothrombin coagulation time.

*Three different batches of thromboplastin were used in order to lessen the margin of error.

†"Sclpven" brand Russell viper venom for this study was supplied by Burroughs Wellcome & Co., New York, in vials of 0.1 mg. and 0.5 mg., with 1 c.c. and 5 c.c. of diluent, respectively, thus making a 1:10,000 solution when diluted.

RESULTS OF STUDY

Using two methods, prothrombin coagulation tests were performed on blood from 71 individuals. The results in graphic form with the diagnoses are given in Figs. 1 and 2. The prothrombin coagulation time, with Quick's method averaged 25.0 seconds, while that of the modified test with Russell viper venom averaged 24.7 seconds.

Fig. 2.—Prothrombin estimation using Russell viper venom and tissue extract.

The greatest variation between the two tests was found in the plasma of an essentially normal individual; by Quick's method the prothrombin time was 5.5 seconds longer than by the modified test with venom. In only six cases was the variation between the two tests more than three seconds.

Statistical evaluation (using the "t" formula of Fisher and Yates) of the results of the two tests gives a value of 1.638, which indicates that the time difference between the two tests is not significant. The prothrombin coagulation times, as determined by these two methods, differed so slightly that for all practical purposes the results obtained may be assumed to be identical.

For the purpose of this study it was considered that prothrombin time over thirty seconds was abnormal. In cases with a prothrombin time of less than 30 seconds it was found that when Russell viper venom was used, the average time of appearance of the fibrin web was 22.9 seconds. This figure closely checks with the average time of 21.7 seconds, as reported by Fullerton.

DISCUSSION

A modified Quick's method, using Russell viper venom instead of tissue extract, has been compared with the regularly used Quick's method for determination of prothrombin coagulation time. Comparison of tissue extract and Russell viper venom is shown in Table I.

TABLE I

	TISSUE EXTRACT	RUSSELL VIPER VENOM
Preparation	Usually prepared from brain tissue (rabbit, etc.) by laboratory in which it is to be used	Dried, sterilized, and packed in sealed vials
Standardization	Must be compared with extracts of known potency or by testing on plasma of known normal prothrombin content. Difficult to obtain extracts of constant potency	Standardized by comparing with a sample of known potency on fowl and horse plasma*
Deterioration	Gradually loses potency	Relatively stable in dry form; in solution it is stable for one month when kept in refrigerator and well-stoppered
End point of test; formation of fibrin web	Makes it difficult to determine because milky appearance of tissue extract obscures early recognition of fibrin web	Clear solution enables determination of fibrin web to be seen easily

*Information supplied by manufacturer.

Included in the study were seven post-partum patients within ten days of delivery. Their average prothrombin coagulation time was thirty-two seconds, which may be considered a borderline prothrombin deficiency. This may have been due to one or both of two factors, namely, loss of blood at time of parturition or a low-grade vitamin K deficiency. It is worthy of note that every one of the post-partum patients had a prothrombin time well prolonged above that of the average (22.9 seconds).

Eleven of the 71 patients studied had prothrombin coagulation times over thirty seconds. Included in this group were two essentially normal females, one patient five months pregnant, one patient with cardiac failure, one patient with cirrhosis of the liver, one patient with chronic ulcerative colitis, one patient with pancreatitis, and four post-partum patients that were still hospitalized.

Russell viper venom is available as a standardized preparation. It simplifies the performance of prothrombin coagulation tests and readings of the end point of fibrin web formation are easier than when tissue extracts of variable potency are used.

CONCLUSIONS

1. Prothrombin coagulation tests were performed on 71 patients with Quick's method and a modified Quick's method using Russell viper venom.

2. The time differences between the two tests were found to be very small and were not statistically significant.

3. The use of Russell viper venom made the performance of the test and the accurate reading of the end point of formation of fibrin web simpler than when tissue extract was used.

A NEW METHOD FOR DETERMINING SPECIFIC GRAVITY OF BLOOD AND BODY FLUIDS*

FRANCIS FÖLDES, M.D., BUDAPEST, HUNGARY

FOR the determination of the specific gravity of blood the exact method of pyknometry can be employed, but on account of its convenience, Hammerschlag's method¹ is often used instead in clinical practice. The specific gravity of colorless body fluids is usually determined by refractometry, based on protein content. Herein is discussed a very accurate method which permits determination of the specific gravity of blood or other body fluids by making use of a small quantity (one to two drops) of blood, exudate, transudate, etc.

In Hammerschlag's method a mixture of chloroform and benzene is employed, the specific gravity of which approximates the expected specific gravity of the blood to be examined. Into this mixture one drop of blood is dropped; if it sinks to the bottom of the vessel, chloroform is added; if it floats on the surface, benzene is added, stirring the whole time, till the drop keeps floating in the middle of the mixture. This indicates that the specific gravity of the blood and mixture is equal. At this concentration the specific gravity of the mixture and hence of the blood is determined by an areometer.

The new method is a simplification of the Hammerschlag method and is carried out by adding one drop of the liquid to be examined (for simplicity's sake blood will be taken as an example), to a mixture of chloroform and benzene contained within a previously calibrated vessel. If the drop of blood sinks to the bottom, chloroform is added; if it floats on the surface, benzene is added, continuously stirring, till the drop floats at the center of the mixture. The specific gravity can then be directly read off from the graduations on the neck of the vessel.

*From the Jewish Hospital, Budapest.

Received for publication, January 25, 1940.

The vessel (Fig. 1) of the blood gravimeter consists of a globe-shaped body and a long slender neck, closed by a glass stopper. Its volume up to the first mark is equal to 25 c.c., or a multiple of this quantity, and is marked "50." Assuming that the gravimeter is filled up to this mark by a chloroform-benzene mixture of a specific gravity 1.050 and a volume of 25 c.c., it follows by the equation $25 \times 1.050 + 1.476x = 1.055 \times (25 + x)$ that 0.297 c.c. of chloroform has to be added to raise the specific gravity to 1.055. Similar calculation discloses the quantity of chloroform necessary to increase the specific gravity to 1.060, 1.065 . . . 1.090. The values calculated are as follows:

SPECIFIC GRAVITY	CORRESPONDING VOLUME
1.050	25.000
1.055	25.297
1.060	25.601
1.065	25.912
1.070	26.231
1.075	26.558
1.080	26.893
1.085	27.237
1.090	27.590

By the equation $25 \times 1.050 + 0.884y = 1.045 \times (25 + y)$ it is possible to calculate the amount of benzene to be added to the 25 c.c. of originally 1.050 mixture, that the latter may decrease to the specific gravity of 1.045, 1.040 . . . 1.030. The values calculated are as follows:

SPECIFIC GRAVITY	CORRESPONDING VOLUME
1.050	25.000
1.045	25.776
1.040	26.602
1.035	27.484
1.030	28.425

The calibration of the blood gravimeter is estimated by using the data of the two columns above. On the one side of the neck of the vessel those volumes are marked which correspond to that amount of chloroform which, when added to the mixture with the original specific gravity of 1.050, increases this up to 1.055, 1.060 . . . 1.090, respectively. On the other side, those volumes are marked, corresponding to which such amounts of benzene have been added that the original specific gravity of the mixture is decreased to 1.045, 1.040 . . . 1.030. It is of advantage to mark instead of the volumes themselves, the corresponding specific gravity values. If the distance between two of the marks is subdivided into five equal parts, differences of one degree of specific gravity can be determined.

The calibrated gravimeter is used as follows: The vessel is filled up to the 50 mark with a chloroform-benzene mixture of 1.050 specific gravity.* The tip of a finger is cleansed and pierced, and one or two drops of blood are sucked up into a thin pipette. After the tip of the pipette has been cleaned, one drop of blood is dropped into the mixture. If the specific gravity exceeds 1.050, the drop sinks to the bottom. While cautiously rotating the closed vessel, chloro-

*The specific gravity of chloroform and benzene being known (1.476 and 0.884, respectively at 20° C.) and marking it 1476 or 884, respectively, the proportion necessary to produce a mixture of 1.050 calculated by the equation $1476x + 884 \times (1 - x) = 1.050 \times 100$ is 28:72. Consequently, 28 c.c. of chloroform and 72 c.c. of benzene are necessary to produce 100 c.c. of a chloroform-benzene mixture of 1.050 specific gravity.

form is added in small quantities till the drop of blood floats at the center of the mixture contained in the globular part of the vessel. At this concentration the specific gravity is read at the graduation. On the other hand, if the specific gravity is less than 1.050, benzene is added to the mixture until the drop floats in the middle.

Fig. 1.

Fig. 2.

Allowing that the specific gravity of chloroform and benzene used for the determination is taken at 20° C., and that the coefficient of the thermal expansion of both^{2, 3} is equal to 0.001, the temperature of the mixture has to be determined after use and has to be corrected accordingly. This is done by subtracting as many points of the specific gravity determined as are above 20, supposing that the temperature has been found to exceed 20° C. Contrariwise, as many points are added as the temperature has been found to be below 20° C.

The method is also suitable for determining the specific gravity of other body fluids. Considering that the specific gravity of body fluids is for the most part below 1.050, another gravimeter (see Fig. 2) has to be calibrated which permits the reading of specific gravity values between 1.029 and 1.004. As a starting point a chloroform-benzene mixture of 1.014 specific gravity is suitable, since it is easy to procure 25 c.c. of it, by mixing 5.5 c.c. of chloroform and 19.5 c.c. of benzene as indicated by the equation $1.476x + 0.884 \times (1 - x) = 1.014$.

By the equation $25 \times 1.014 + 1.476x = 1.019 \times (25 + x)$ the amount of chloroform necessary to add to the mixture to arrive at a specific gravity of 1.019, 1.024 . . . 1.029 is calculated. The values are as follows:

SPECIFIC GRAVITY	CORRESPONDING VOLUME
1.014	25.000
1.019	25.263
1.024	25.543
1.029	25.829

By the equation $25 \times 1.014 + 0.884y = 1.009 \times (25 + y)$ the amount of benzene can be calculated by the addition of which the specific gravity of the subsequent mixtures can be regulated at 1.009 and 1.004. The values calculated are as follows:

SPECIFIC GRAVITY	CORRESPONDING VOLUME
1.014	25.000
1.009	26.000
1.004	27.083

Allowing that the specific gravity of the body fluids, which may have to be determined, varies between the values of 1.004 and 1.090, two separate calibrated vessels of which the one is graduated from 1.004 to 1.029 and the other from 1.030 to 1.090 suffice for determining the specific gravity of body fluids encountered in clinical practice.

The figures obtained by the blood gravimeter were controlled several times by comparing them with the values obtained by pyknometry. The difference found never exceeded one to two points.

SUMMARY

A new method suitable for simple and reliable determination of the specific gravity of blood and body fluids has been described. Although differing only slightly from the results obtained by pyknometry, this method is simple and easy to use, and is especially valuable for making estimations in a large number of cases. The simplicity of the method permits its use by the clinician at the bedside. One to two drops of the substance to be examined are sufficient. Besides the previously calibrated gravimeter, only chloroform, benzene, and a thermometer are necessary to practice it. The low cost of the method is a further advantage. Besides its clinical application the method is sufficiently reliable to be used for comparative investigations of the change of specific gravity in different types of disease and may, therefore, be used with advantage for scientific purposes also.

A NOTE ON THE VISSCHER-BOWMAN CHEMICAL TEST FOR PREGNANCY

HENRY G. HADLEY, M.D., WASHINGTON, D. C.

THE Visseher-Bowman test¹ was thought by some to be of value in the diagnosis of early pregnancy.¹ It is performed by adding one drop of 1 per cent hydrogen peroxide, five drops of 1 per cent phenylhydrazine hydrochloride, five drops of 5 per cent methyleyanide, and five drops of concentrated hydrochloric acid to 1 c.c. of urine, then heating in a water bath for twenty-five minutes. A flocculent brownish-red precipitate is indicative of a positive reaction.

Sheehan² decided that the effect of hydrochloric acid with heat was responsible for the positive reaction and found that over 60 per cent of male urine gave positive results. These results agree with Krieger,³ who considered the reaction due to nonspecific reducing substances and not to the hormones of the anterior lobe of the pituitary. These nonspecific substances appeared to be reducing carbohydrates, particularly in the presence of albumin, urinary pigments, and other reducing substances, especially if concentrated.

The urines of 232 persons were tested, 35 being urines of pregnancy and the remaining being urines of 77 males and 120 nonpregnant females. The results showed that there were as many positive reactions in the males as in females. About 75 per cent of the total group were positive. Apparently the test does not show the presence of hormone nor is it a specific test for pregnancy. The length of time of boiling was not found to influence greatly the results, except that where the boiling was continued longer, a greater percentage of positive reactions was obtained in both males and females. Apparently the reaction was produced by nonspecific substances in the urine, as a greater percentage of positive results were obtained from normal urine and from urines of persons with diabetes by adding solutions of dextrose.

CONCLUSION

This test appears to be of no value because nearly as many positive results were obtained from the urines of males and nonpregnant females as from the urines of pregnant females.

A SIMPLE AND INEXPENSIVE MICROTITRATION APPARATUS*

ESPECIALLY USEFUL FOR TITRATING CULTURE MEDIA

E. S. KING, M.D., F.A.C.P., AND L. L. CHASTAIN, M.S., WAKE FOREST, N. C.

THE need for a simple, yet accurate and convenient, apparatus for titrating culture media resulted in our design. It is especially useful for making the titration necessary for the adjustment of the reaction of culture media by the colorimetric method, although it may be used for any titration where small amounts of exact alkali or acid are required. It is equally useful also in the adjustment of the reaction of culture media by the Fuller method.

FIG. 1.

The apparatus consists of an ordinary ring stand, two clamps, a 1 c.c. pipette graduated in hundredths, a 2 c.c. hypodermic syringe, and a short piece of rubber tubing. The pipette (A) is held in a vertical position by an ordinary burette clamp. The pipette is connected by rubber tubing to the syringe (B) held in a horizontal position in a simply constructed wooden block (C) by a second burette clamp. The wooden holder for the syringe is a split block of wood

*From the Departments of Bacteriology and Physiology, School of Medical Sciences, Wake Forest College, Wake Forest.

Received for publication, May 2, 1940.

through which a hole, just large enough to accommodate the barrel, has been bored. The two portions of the split block are held together by bolts with wing nuts. A square of tin to which a nut has been soldered is tacked across one end of the block; a long screw (*D*) is threaded through this nut and is fastened to the plunger of the syringe by one end of a small one-hole rubber stopper, to which it is glued, and into which the screw is threaded at the opposite end. The same arrangement may be made merely by sinking the nut through which screw (*D*) passes into the block. The level of the fluid within the pipette is regulated by turning the screw (*D*) which forces the plunger in or out. A feature of some value is that the syringe is on the same level as the upper figures on the pipette; so that both are on the same level with the eyes when the instrument is being used.

Our use of the instrument has indicated that it has the distinct advantage of being more accurate than manipulation of the pipette by hand in the usual way, since the expulsion of fluid from the pipette is always under positive and complete control. If necessary, a fraction of a drop may be used with ease, a thing which is rather difficult without this control.

The apparatus may be constructed at a very moderate cost. A ring stand may be purchased for 45 cents, clamps for 35 cents each, syringe for \$1.25, and the pipette for 25 cents. The wooden block can be made in the shop in a few minutes at almost no cost. The total cost would be approximately \$2.65.

A SIMPLE ABSORPTION BULB FOR USE WITH AN ORDINARY SYRINGE IN DETERMINING OXYGEN OF THE AIR IN AN OXYGEN TENT*

FREDERIC E. HOLMES, CINCINNATI, OHIO

USUALLY it is not necessary to determine the oxygen content of the atmosphere of the oxygen tent with the precision attainable with the more refined gas analysis apparatus. Numerous simple forms of apparatus have come into use. Henderson and Greenberg¹ employed an ordinary syringe with simple accessories. The reagent for the absorption of oxygen was a solution containing sodium hydrosulfite, which was drawn into the syringe after measurement of the volume of the sample. Hoechstetter² used an apparatus somewhat similar in principle, consisting of two syringes, the lower one of which contained copper screen and a solution of ammonia and ammonium chloride. In each of these devices, the volume of the sample was measured at a pressure dependent upon the weight of either the barrel of the syringe and its accessories or the plunger. After absorption of oxygen the volume of the residual gas was measured supposedly under the same pressure. However, in practice, using Henderson's apparatus, we found it difficult to eliminate entirely sticking of

*From the Children's Hospital Research Foundation and the Department of Pediatrics, College of Medicine, University of Cincinnati.

Received for publication, May 31, 1940.

the plunger, and since there was no way of measuring the pressure of the gas in the syringe, we were never certain that we had obtained the same pressure for both readings. While it might be possible to select a syringe free of any tendency to stick, it is obviously advantageous to be able to use any syringe that happens to be at hand. By means of the manometer fused to the absorption bulb shown in Fig. 1., the operator is enabled to bring the residual gas to the same pressure as the original sample, despite any resistance that is likely to occur.

Fig. 1.

The apparatus consists of an ordinary syringe, preferably of 10 c.c. capacity, an absorption bulb of about 60 c.c. capacity, and a manometer with an expansion bulb as shown. The sizes of parts may be obtained by reference to the accompanying scale, but these dimensions are not critical. The small tubing constituting the manometer proper extends to a point above the top of the stopper in the absorption bulb. This one-hole rubber stopper and the solid stopper at the top of the manometer are indicated by diagonal shading. The neck of the absorption bulb is tapered to fit a O or OO stopper, thus insuring a snug fit and a minimum change in volume due to distortion of the stopper in inserting the tip of the syringe. The apparatus is supported in a hole in a wooden block.

To prepare the bulb for use, light copper turnings are stuffed into it through the neck, and the solution is poured onto the turnings until it reaches the level of the bottom of the stopper. The stopper is then inserted, and a small piece of glass rod is used to plug the hole. Any excess solution may be rinsed off from the outside of stopper or bulb. The copper turnings should fill the bulb, but should not be packed tight enough to impede displacement of all gas bubbles by the solution after absorption. The solution is made according to Badger³ by saturating a mixture of one part of concentrated ammonium hydroxide and two parts of water with ammonium chloride. When the apparatus is not in use, the top of the manometer is closed by a solid rubber stopper to prevent slow absorption of oxygen from the air. This stopper is removed during analyses.

A determination is made in the following manner: A representative sample of more than 10 c.c. is obtained in the syringe. The plunger is brought to the 10 c.c. mark and held rigidly in this position while the tip of the syringe is inserted into the hole in the stopper and while the level of liquid in the manometer is marked by a glass-marking pencil or by a small clamp placed on the manometer. The plunger is then pushed down slowly until the sample has been forced into the bulb; it is held there for a few seconds, and then it is lifted until the liquid in the bulb touches the bottom of the stopper. This operation is repeated until the volume of the residual gas is constant. Usually four transfers of the sample into and out of the bulb are enough. The plunger is finally raised (or lowered) until the liquid in the manometer has been brought back to the original mark, and the volume of the residual gas is read on the graduations on the syringe. The difference between the initial reading (10 c.c.) and this final reading represents the volume of oxygen absorbed.

Theoretically, there should be some error due to the absorption of oxygen from the lumen of the tip of the syringe and from any small bubble that may be present in the hole of the stopper, but actually this error is too small to detect. An expected error due to change in level of the liquid when the tip of the syringe is pushed into the stopper is also too small to be detected. Usually no error is introduced by a rather large bubble below the stopper because it consists of inert residual gas from which the oxygen has been absorbed. Determination of the oxygen in air or in known mixtures of air and pure oxygen are usually accurate to within 1 or 2 per cent of the total volume of the sample.

Although the open manometer is less compact and offers less than complete protection of the solution from contact with the outside air, it is superior to a closed manometer in ease of manipulation and in freedom from the effects of changes in temperature.

A satisfactory clamp for marking the position of the meniscus in the manometer at the time of the first reading may be made by opening out a paper clip until it can be placed over the glass tubing, and then bending the long loop around the tube to prevent its slipping off.

A SIMPLIFIED DETERMINATION OF BLOOD PROTHROMBIN LEVELS IN THE NEWBORN*

CARL P. HUBER, M.D., AND JACK C. SHRADER, M.D., INDIANAPOLIS, IND.

RECENT studies have aroused interest in the relationship of vitamin K to various hemorrhagic tendencies in the human being. In the adult these have been largely concerned with bleeding states in obstructive jaundice.¹⁻³ In the newborn infant they have been concerned particularly with hemorrhagic disease. The importance of vitamin K in the establishment and maintenance of adequate prothrombin levels in the blood has been verified.

Study of the prothrombin content of the blood of newborn infants has shown that considerable variability exists in the normal infant during the first week of extrauterine existence.⁴⁻⁸ In general, this is manifested as a drop in prothrombin level during the first few days of life followed by a return to at least the original level during the second week.

Routine study of a large series of infants has been complicated by the necessity of repeated venepuncture to obtain blood for study. More recently, Bray and Kelley⁹ and Kato¹⁰ have reported the use of capillary blood obtained by heel puncture as giving satisfactory results. During the past nine months we have been using a modification of the Smith¹¹ bedside test as a simple clinical method for evaluating the prothrombin factor in blood of the newborn.

METHOD

A total of 20 c.mm. of thromboplastin extract are placed on a clean glass slide. Blood is obtained from the infant to be tested by heel puncture. Twenty cubic millimeters of blood are drawn into a blood pipette and immediately transferred to the drop of thromboplastin on the slide. A stop watch is started at this time. The blood and thromboplastin solution are mixed, and the drop is pricked every second with a stylus until a firm, fibrin strand adheres to the point. The interval in seconds is recorded as the prothrombin clotting time. A normal control is run in the same manner using adult finger blood. The prothrombin level is expressed in per cent of normal using the formula suggested by Smith and co-workers:

$$\frac{\text{Clotting time of control}}{\text{Clotting time of unknown}} \times 100 = \text{clotting activity in per cent of normal.}$$

The technique of making the heel puncture which was found to give the best results is as follows: The infant is cradled on the left arm while holding the infant's left foot in the left hand. The heel is sponged with alcohol and dried carefully. Using a No. 11 knife blade the puncture is made slowly and deliberately on the posteromedial edge of the heel at a depth of approximately

*From the Department of Obstetrics, Indiana University Medical Center, Indianapolis.
Received for publication, August 3, 1940.

$\frac{1}{8}$ inch. The left leg is then lowered into a dependent position, and a drop of blood immediately begins to form. The infant is replaced in the crib and blood is drawn into a pipette to the 20 c.mm. mark. Delay in obtaining the blood and squeezing the heel will shorten the prothrombin clotting time. A second determination cannot be made from the same bleeding point as the blood will always clot considerably quicker than the first drop obtained.

The thromboplastin extract is prepared in the following manner: Fresh sheep or swine lung is ground in a domestic meat grinder and placed in a large beaker. To this is added 1 c.c. of normal saline per gram of ground lung. The lung-saline mixture is stored overnight in the refrigerator. It is then strained through a double layer of broadcloth. The saline extract is placed in small test tubes and securely corked. These tubes are stored in the freezing compartment of a refrigerator where the thromboplastin extract retains its potency for at least six weeks. When ready for use, a tube is allowed to thaw and the extract is used at room temperature.

Chart 1.

Chart 1.—Average values in per cent of normal clotting activity on the various days of the neonatal period in 114 infants.

Chart 2.

Chart 2.—Curves showing the variation in clotting activity in four normal infants.

RESULTS AND COMMENT

We recognize that with this method we are not obtaining an accurate determination of the prothrombin level of the blood, but rather a summation of several factors, including particularly the amount and convertibility of prothrombin. We feel that for practical purposes such a measure of the ability of the blood to clot in the presence of an excess of thromboplastin will indicate those infants in whom a critical deficiency exists.

Using this method we have routinely determined the clotting activity in a series of 114 infants. The infants were tested every other day during the first ten days of life, or for longer periods if they remained in the hospital. Chart 1 illustrates in per cent of normal clotting activity the average level for each day of life in the total group of 114 infants. It will be noted that the lowest levels

are reached forty-eight to seventy-two hours after birth. By the end of the first week the average values are well within the normal range and seem to be maintained at that level.

Considerable variation exists in individual infants as shown in Chart 2. The four infants whose curves are illustrated were all full term, delivered without incident, breathed spontaneously, and were breast fed. In reviewing our charts we find no evidence of consistent differences in the clotting activity of premature and full-term infants. We do, however, find suggestive evidence that there is a seasonal variation in the type of curve. In 10 infants delivered consecutively during November, 1939, the average low reading was 45 per cent, while in 10 infants delivered during March, 1940, the average low reading was 12 per cent of normal clotting activity. This observation is not surprising in view of the probable differences in diet of the average patient during the summer and winter months. Further study of this phase is being made.

Chart 3.

Chart 3.—Typical curves illustrating the marked drop in clotting activity in the blood of some normal infants.

Chart 4.—A prolonged low prothrombin level in an infant with a bleeding tendency showing a rapid response to a vitamin K preparation.

Chart 4.

Two typical curves of a different type are shown in Chart 3. The striking drop on the third day is obvious. Both of these infants were normal, and there was a rather prompt return of the prothrombin clotting time to normal. It is suggested that any unusual trauma to infants showing such a curve might well precipitate serious bleeding. This may be a factor in increasing cerebral injury associated with difficult delivery or prolonged asphyxia, particularly where an increase in the symptoms appears twenty-four to seventy-two hours after delivery.

That vitamin K will correct this decrease in clotting activity and that, if administered early, it will prevent the drop is indicated by recent reports in the literature,^{6,7} as well as by investigations in progress on our service. In Chart 4 we illustrate the rapid rise to normal level of the clotting activity in an infant who, coincident with the low levels found during the first five days of life,

passed bloody mucus from the bowel and vomited a blood-streaked material. Therapy consisted of 1 mg. of 2-methyl-1, 4-naphthoquinone (Squibb) in corn oil, given orally on the fifth and sixth days as shown. No further bleeding appeared after administration of this material.

The apparent relationship of a low prothrombin content of the infant's blood to hemorrhagic disease of the newborn, and very probably to other bleeding tendencies, indicates the desirability of an increasing number of observations of this relationship. This is particularly true in view of the reported efficacy of vitamin K in the therapy of these infants. It is with this thought in mind that we are presenting a simplified procedure for clinical evaluation of the prothrombin level. It can be readily performed without special laboratory facilities and does not require venipuncture on the infant.

CONCLUSIONS

1. A simplified procedure for the determination of prothrombin levels in the blood of the newborn infant is described.
2. With this procedure a decrease in clotting activity is demonstrated and reaches a maximum the second and third days of the neonatal period.
3. In the normal infant there is a spontaneous return to normal clotting activity by the beginning of the second week of life.
4. A seasonal variation in the degree of prothrombin deficiency is suggested. This appears to be most marked during the early spring.

ON THE MEASUREMENT OF EXTRACELLULAR FLUID VOLUME WITH THIOCYANATE AND BODY FLUID ANALYSES IN 33 NORMAL INDIVIDUALS*

J. D. STEWART, M.D., AND G. M. ROHRKE, B.A.
BOSTON, MASS.

IN 1934 Crandall and Anderson¹ reported results of studies on determination of body fluid available for solution of thiocyanate. They concluded that consistent results could be obtained in the same individual, and that with qualifications the solvent measured could be considered extracellular fluid. The thiocyanate ion when injected intravenously as sodium thiocyanate, or when taken by mouth as the sodium or potassium salt, diffused rapidly into water of plasma, red blood cells, transudates, and gastrointestinal secretions but not into cerebrospinal fluid. The thiocyanate was found to be excreted from the body quantitatively through the urine. Laviètes, Bourdillon, and Klinghoffer² showed that thiocyanate, sucrose, and inorganic sulfate are distributed through approximately the same fraction of body fluid. This fraction was found to make up about 20 per cent of the weight of normal persons, and was considered as composed in all probability chiefly of extracellular fluid. These workers discovered that thiocyanate becomes distributed in serum partly in bound form, and devised a formula to correct for consequent unequal distribution in calculating extracellular fluid volume. Gregersen and Stewart³ developed a technique for simultaneous determination of plasma volume and extracellular fluid volume, based on the spectrophotometric determination of concentrations of the blue dye of Gregersen's plasma volume method⁴ and the thiocyanate of the extracellular fluid volume method.

We have used the thiocyanate method extensively for determining extracellular fluid volume in normal subjects and in patients and animals with disturbances in water balance. The present study deals with technique we now use in making the determination, and reports illustrative normal values.

METHODS

Reagent grade sodium thiocyanate is dried at 100° C. until constant in weight. Fifty grams are weighed out, dissolved in 500 c.c. of distilled water, and the solution is filtered. The filter paper and funnel are washed with 250 c.c. of warm distilled water. The solution, then having a volume of about 750 c.c., is sterilized by boiling in a liter, covered, volumetric flask for thirty minutes. After cooling, the solution is made up to volume with sterile distilled water. The solution is put up in 25 c.c. quantities in sterile test tubes capped

*From the Surgical Laboratories of the Harvard Medical School at the Massachusetts General Hospital, Boston.

Received for publication, September 4, 1940.

with Davol baby bottle caps No. 150. Before using the solution, 25 c.c. are given to a dog intravenously, and a precautionary bacteriologic culture of a sample is made to exclude chance contamination. The solution keeps several months without deterioration. On using it the solution must be perfectly clear.

Chart 1.—Thiocyanate diffusion curves after intravenous injection in normal individuals, constructed from plasma concentrations.

For injecting the thiocyanate solution into a vein a calibrated 10 c.c. or 20 c.c. syringe is used, the syringe and needle having been sterilized by autoclaving. The syringe and needle are washed with three or four 2 c.c. quantities of blood before withdrawing the needle from the vein. A vein in the opposite arm is used in taking samples after this injection, and five samples of blood of 5 c.c. each are taken, preferably at intervals of ten; twenty, thirty, forty, and fifty minutes. In making the determination in adults as a rule 20 c.c. of the 5 per cent solution are given. In children or in dogs, and in adults upon whom the determination has previously been made within three days, 10 c.c. are injected.

In samples of serum withdrawn subsequently thiocyanate concentration is measured in a colorimeter, using the method of Crandall and Anderson,¹ or the spectrophotometric method of Gregersen and Stewart.³ In either case the filtrate obtained after precipitation of serum protein must be clear before producing color by addition of the ferric nitrate reagent. If thiocyanate has been given within a week, a pre-sample must be taken and its thiocyanate concentration deducted in using the colorimetric technique. In the spectrophotometric measurement the thiocyanate content of the pre-sample is automatically deducted, since the determination measures increase in optical density

of the post-sample compared with the pre-sample. We now use only the intravenous technique in giving sodium thiocyanate, since we have found the results much more consistent than with the oral method. In no case has evidence of toxic reaction to the injected sodium thiocyanate been observed. However, we never inject more than 20 c.c. of 5 per cent sodium thiocyanate at one time, and have not produced levels higher than 15 mg. per cent in the blood.

CALCULATIONS

An important point in technique relates to the diffusion curve which is constructed after the intravenous injection of sodium thiocyanate. For the first fifteen to twenty-five minutes the concentration in the blood serum falls rapidly. The curve then assumes a different form, and the subsequent gradual decline in serum concentration depends on urinary excretion. To get accurate results consistently we find it necessary to obtain enough samples of serum to plot the two components of the curve. The point at which the two components merge, indicated by the arrow in Chart 1, is then considered as the concentration in the serum after uniform diffusion in extracellular fluid has resulted. Results may be quite variable if only a single reading is made thirty or forty minutes after injection, for in abnormal conditions, such as deranged water balance and anesthesia, the second component of the curve, as well as the first, may have a variable slope. This point is indicated in the series of curves shown in Chart 1.

In calculating fluid available for solution of thiocyanate, considered as extracellular fluid plus water of red blood cells, we use the simple formula (formula A):

$$\text{c.c.} = \frac{\text{mg. SCN given} \times 100}{\text{mg. \% concentration SCN in serum}}$$

This uncorrected formula gives results of practical value, though it ignores such considerations as partial binding of thiocyanate by serum protein and lower concentration in red blood cells than in serum due to lower water content in cells. If plasma volume and hematocrit have been determined at the same time as extracellular fluid volume, then the formula of Lavietes, Bourdillon, and Klinghoffer² may be used (formula B):

$$\frac{\text{Extracellular fluid volume} = (\text{mg. SCN retained in body}) - (\text{conc. in serum} \times \text{blood vol.}) + (\text{serum vol.})}{(100/110) (\text{conc. in serum})}$$

This formula introduces too great an error if serum volume and whole blood volume are assumed to be constant fractions of body weight, particularly in the conditions of deranged hydration where the determination would be of most interest. There is undoubtedly error also in computing whole blood volume from plasma volume and hematocrit of venous blood, due to the higher plasma content of capillary blood resulting from axial streaming of corpuscles.

In Table I are presented data from 33 normal physicians and students, and patients awaiting elective surgical procedures, studied in the resting post-absorptive state. Average values for the group are computed. Values for plasma volume⁴ and extracellular fluid volume are expressed in cubic centi-

meters and in relation to weight and surface area. Data headed extracellular fluid volume (formula A) are calculated by the original formula of Crandall and Anderson.¹ In the column headed extracellular fluid volume (formula B), the formula of Laviètes and others is used, and the values are lower inasmuch as water of red blood cells is deducted. This difference is partially offset, however, by the correction the latter formula makes for binding of thiocyanate by serum protein. Hematocrit readings were made by adding 4 c.c. of blood to 1 c.c. of 1.1 per cent sodium oxalate solution and centrifuging in hematocrit tubes until no further change in the reading occurred, precautions being taken against loss of carbon dioxide. Serum sodium was determined by the gravimetric method of Butler and Tuthill,⁵ serum chloride by the method of Wilson and Ball,⁶ total nitrogen of plasma by the macro-Kjeldahl method.⁷ Oxygen capacity was determined, using heparinized venous blood drawn without stasis and equilibrated with room air at room temperature.⁸

SUMMARY

1. Modifications are described in the method of determining extracellular fluid volume by the thiocyanate technique.
2. Body fluid analyses in 33 normal individuals are reported.

MEDICAL ILLUSTRATION

SHARPNESS CONSIDERATIONS IN MAKING SCIENTIFIC ILLUSTRATIONS*

LLOYD E. VARDEN, A.R.P.S., BINGHAMTON, N. Y.

NO ONE will doubt the value of sharp photographs when used for scientific purposes. The very reason for using photography in illustrating case records or investigations dictates that sharpness should be a prime requisite, because the oddity of many studies calls for photographic illustrations in order to convey properly the full meaning of the problems or disclosures at hand. There is no better way to present a new situation than by photographic means, but so often we find that pictures of immense value to the individual investigator are of no value to other workers and students. By this, I mean that an investigator intimately concerned and entirely familiar with a given undertaking is able to see in a picture the real meaning it has in connection with some particular point, while to a more or less neutral or uninformed worker the picture will not have the same significance unless it clearly depicts the situation under observation. To do this the image must be sharp, and the sharper the better.

Of course, there are several considerations to be taken into account when attempting to achieve a high degree of perfection in photographic illustrating. The proper films must be chosen, the lighting arrangement on the subject must be correct, proper exposure and development should be given, and many other fundamentals should be executed exactly. Most of these requirements are topics within themselves. However, our interest in them at this time will be limited to the extent of the effect that these might have upon the subject of sharpness. They will be discussed as incidental matters at the points where they appear in the discussion at hand.

To define sharpness is not as easy as one might imagine. In general, we all have a common understanding of what is meant by the term. But other visual factors come into play that may cause confusion of the real issue. For example, from a given negative two prints can be made—one on soft paper and the other on hard. To an untrained observer and to many experienced people, the print on hard paper will always be interpreted as the sharper, whereas actually it can easily differ only in the degree of contrast. This same confusion is experienced to a less pronounced degree by viewing prints under different levels of illumination, where the variations in brightness result in a change in visual acuity.

I should not care to take the stand that *effective* visual sharpness cannot be altered by such means. On the contrary, it has always seemed to me that the

visual definition of a photograph is intimately bound with the *ease* of ready interpretation. On the other hand, from a more critical standpoint, ease of interpretation (or readability) and actual definition are distinct matters. I shall have occasion to refer to this later.

In the practical production of sharp photographs there are several distinct and unquestionable factors. First, there is the subject itself. It will be agreed that the ultimate goal is to record all of the detail in the original subject and often, if possible, to exaggerate the ease of recognizing this detail by pure photographic possibilities, for example, exaggeration by contrast increase, bettering tone separation by filters and stains and other methods. From a practical standpoint the subject matter must be observed carefully because a working tolerance exists that in some cases permits workmanship of considerable mediocrity, while in others the tolerance is so small that exacting requirements must be complied with at every step. Probably this point deserves exemplification. Imagine that a department for years has been required to photograph gross objects having only massive details. For this work a lens and camera of average quality, adjusted quickly by unaided vision, would perhaps be found entirely adequate. Now suppose the same department is called upon to supply 8 by 10 photographs of some small, highly detailed sections of gross objects. The same equipment and methods of working in this case, as used for the mass-detailed gross objects, would certainly be found lacking in the capacity to produce sharp results. For this reason it is a good idea when making photographs of any type to attempt to procure the maximum sharpness at all times. This may require the use of reference objects possessing fine details in many cases, but the need for such simple accessories cannot be considered as a barrier to the general adoption of the principle of maximum sharpness at all times.

In arranging the lights before making a picture one should profit by the experience gained in the use of the microscope. In microscopy we are concerned with subjects of exceptionally fine details. It is well known that the finest details, especially when the magnification limit of the instrument is employed, are readily lost by a slight shift from the optimum direction of the principal light beam. To be sure, when making photographs of gross objects the placement of the light source is not so critical as in high-power microscopy, but the fact remains that when fine details within the mass areas of a gross object must be recorded, the judicious use of lights is important. It is observed by most prolific workers that diffuse light sources, although probably giving slightly less than optimum results, will permit more tolerance in placement than specular (condensed or directionally reflected) sources. However, in both cases it is usually true that the lights should not be placed so close as to produce glare and should be at average angles between the horizontal and perpendicular positions, that is, around 45 degrees.

Perhaps the most important equipment consideration is the lens of the camera. It is universally recognized that there exists a wide variation between different types and makes of photographic objectives as far as sharpness is concerned. It is further known that in practice the wide aperture lenses (of a given focal length) are usually less capable of producing a sharp image over a wide field than lenses of smaller aperture. Theoretically, the reverse is true,

for the theoretical resolving power of an objective increases with an increase in numerical aperture. However, lens makers find that a sacrifice is usually made in sharpness when the aperture is very large. At the same time, when the aperture is very small sharpness again is lost, owing to the introduction of diffraction. Apart from this generalization, objectives of poor quality most frequently are the low price types in which insufficient correction has been introduced either in the design or in the grinding of the components. A lens of good make is generally expensive, but because a lens is expensive does not give assurance that it will be of the highest possible sharpness. The best practice is to select a lens from a reputable manufacturer's catalog on a trial basis. If the lens is found to perform the duties required in one's work, nothing more can be asked. If it does not comply with one's requirements, another lens can be tried. At this point it should be said that lenses of good make are in most cases capable of giving better definition than one will find possible to utilize in the photographic process. The limit of film resolution is much lower than the best lens resolution, and even the average good lens has better resolving power characteristics than the average negative film.

In spite of the fact that good lenses exceed the resolving power of most negative materials, a lack of sharpness is observed readily in much of the photographic work produced in biological departments. There must be reasons for this beyond the equipment problem, the chief one being the improper use of the equipment, especially in focusing the camera image.

Focusing is accomplished habitually by simple, unaided visual means in most departments. That this is a bad practice when optimum sharpness is imperative cannot be stressed too emphatically. When ground-glass focusing cameras are employed, it is often advisable to rub the ground glass with vaseline in order to reduce the tendency of the coarse texture to break up the image detail. Focusing should then be done with a magnifying glass of sufficient power to enable clear distinction of the finest details. At every step the perfection of focusing should be checked. If a camera without a focusing ground glass is used, the focus should be checked by placing a section of ground glass in the film plane and examining the image with a magnifier. This is all-important since print sharpness is directly dependent upon negative sharpness.

Upon procuring critical sharpness in the image plane by the proper selection and use of equipment, the next step is to record the image on film with as much fidelity as possible. Naturally, films of maximum ability to record fine details, or those having the highest resolving powers, are ideal and should be selected when other factors permit. By other factors is meant emulsion speed requirements, color sensitivity, and so on.

The resolving power of a film emulsion is difficult to express exactly, since considerable variation exists in its evaluation by different observers. Skilled workers can determine resolving power within 10 per cent of each other, whereas those who are unskilled have difficulty in arriving at results within 30 per cent variations. As a result the resolving powers of Agfa emulsions are arranged in groups, each group differing from the next by about 25 per cent. An emulsion listed in any group will have a resolving power within the limits for the

group, but some films will have slightly better resolving power than others of the same class. The general classification as it now stands is given below:

40 to 50 Lines per mm.

Ultra-Speed Panchromatic, 35 mm.

Superpan Reversible, 35 mm.

The resolving power of an emulsion is a direct expression of its ability to register fine detail. In order for the complete possibilities of the emulsion to be realized in practice, however, the sharpness factors that have already been pointed out must be considered carefully, especially the focusing factor.

After a film of given laboratory determined resolving power is selected for use, it must be exposed and developed properly if good picture quality is to be expected. This fact is well known. But it is not well known that camera exposure and development, within reasonable limits, have little bearing on the sharpness of the final negative image. Of course, when light falls upon an emulsion there are many reasons to cause one to assume that exposure and development should be critical for optimum sharpness. We know that irradiation within the emulsion by reflection and refraction of the light, and halation by back reflection will promote image spread and tend to merge the details. We know further that certain developers result in coarser-grained images than others, and that developed contrast and fog level also affect clarity of definition. However, as was pointed out earlier in this discussion, a distinction must be drawn between ease of interpretation and actual definition. It has been found that exposure and development factors have little bearing on the accuracy of determining emulsion resolving power. This alone does not mean that in practice these points should be ignored. Surely it is more desirable to have a negative in which the details are well separated by clean-cut contours, and at a density and contrast level that enable ready printing. On the other hand, it is enlightening to know that it is not so important as was once thought to have critical exposure and development in order to utilize all the resolution that an emulsion possesses.

Positive paper prints are inevitably made from negatives in biological photography. In this step much sharpness can be lost unless an exacting technique is used. The two principal methods for making paper prints, that is, by contact and by projection, involve much care. For example, in making contact

FIG. 1.—RESOLUTION CHART

The figures indicate the number of lines per millimeter in the chart. To determine the number of lines resolved by the film, multiply the corresponding number by the reduction ratio.

To aid in determining the reduction ratio, the box surrounding these instructions has been made exactly 100 millimeters in length inside dimensions.

prints we often find workers simply holding by hand, a sheet of paper against the negative on the printer top, apparently without knowing how necessary it is to get uniform and intimate contact between the developed negative and the paper emulsion. That this factor is of prime importance is borne out by the care photoengravers take in getting a good strong contact when making prints

from half-tone or line negatives. In the graphic art industry, contact printing is practically always accomplished by the use of vacuum frame printing devices. Actually, the details that are necessary in such work are of a much greater order than 50 lines per millimeter. This is the average resolving power of negative emulsions; therefore, when making contact prints from sharp negatives of biological subjects, for example, it is often necessary to get as good contrast as required in graphic art work. To accomplish this effectively and without the use of a vacuum, a strong spring contact printing frame can be employed to hold the negative and paper. This frame is held at a distance of about 6 or 8 feet from a light source approaching a point, such as an automobile headlight lamp or a clear bulb Mazda lamp. In this way an almost parallel light is used that has less tendency to spread the image detail when the shadow image of the negative is formed on the surface of sensitized paper.

In contact printing it is imperative to use glossy paper if the foregoing conditions are to mean anything. Intimate and uniform contact against a rough surface paper is indeed difficult, if not impossible.

In projection printing a more serious problem arises in attempting to retain in the enlarged print all the detail in the original negative. To begin with, the resolution of detail in a negative can easily give an appearance of absolute sharpness and yet upon projection it may break down. Such a condition is often experienced in amateur box camera photography. Visually, box camera negatives can be very sharp and can give contact prints that appear sharp. However, upon enlarging any negative image made with a simple lens, definition progressively decreases, assuming a constant print viewing distance. The real limiting factor is the acuity of the visual mechanism. It is well known that the optics of the human eye is imperfect; nevertheless, an acuity corresponding to a resolving power of about 150 lines per inch is not uncommon. When the details of a print from a given viewing distance appear fuzzy, it is obvious that the photographic sharpness limit has been exceeded. Contact prints can be well within the sharpness limitations of the eye, but unless negatives of a high order of definition are acquired and this carried through to the print, not many diameters of enlargement are permissible before the eye will be capable of detecting fuzziness. If the viewing distance is increased, a visual improvement is naturally effected from the standpoint of visual sharpness only, for an increase in detail does not accompany this improvement.

The elements of projecting negative images in order to retain as much definition as possible may be listed for convenience, since most of them are self-explanatory. They are:

1. The type of enlarger
 - a. Diffusion types give softer images
 - b. Condenser types give sharper images
2. The amount of scatter and extraneous light within the enlarger system
 - a. Small negatives should be masked off
 - b. The interior must be as nonreflecting as possible
3. The lens
 - a. Should be of high quality.
 - b. Should be free of dust and surface scum

- c. Should be stopped down to the point of greatest sharpness. This can be determined by means of a focusing tester, which is simply a negative of high contrast having clean-cut details that enable a sharp focus to be seen. This is aided further by the use of a magnifier.

In conclusion, it is evident that if optimum sharpness is to be attained, considerable care must be exercised, for fewer problems are critically concerned with equipment and materials than are dependent upon pure technique.

Erratum

On page 1158 of the April number of the JOURNAL in the article by Evan W. MeChesney, Ph.D., Kimball D. Spragne, A.B., and Irvine H. Marshall, M.D., entitled "The Effect of Sulfanilamide on Acid-Base Balance," the twelfth line should read: "In this sample the *hydroxyl*-ion concentration has increased twentyfold from the previous sample" instead of "In this sample the *hydrogen*-ion concentration has increased twentyfold from the previous sample."

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

LYMPHOBLASTOMA, Follicular, Baggenstoss, A. H., and Heck, F. J. Am. J. M. Sc. 200: 17, 1940.

A clinical and pathologic entity variously called "giant follicle hyperplasia of lymph nodes and spleen," "giant follicular lymphadenopathy," and "follicular lymphoblastoma" has been described in the literature in recent years with increasing frequency. The condition is characterized by an insidious onset with regional or general lymphadenopathy, splenomegaly, the absence of anemia or abnormal cells in the blood, and by the great radio-sensitivity of the lesions. The average duration of life after the appearance of the disease is four and a half years, but two patients have lived as long as seventeen years with this disease.

The characteristic histologic changes occurring early in the disease consist of an increase in the number and size of the follicles of the lymph nodes and of the Malpighian corpuscles of the spleen. There is a tendency toward fusion of the follicles, and the lymphatic sinuses are generally narrowed or obliterated.

There is a superficial resemblance between the histologic appearance of follicular lymphoblastoma and the histologic appearance of hypertrophy of the secondary centers of lymph nodes resulting from toxic or inflammatory conditions. The histologic criteria which enable the histopathologist to distinguish the two conditions are outlined.

In certain rare instances in which the histologic appearance is not typical of either follicular lymphoblastoma or inflammation, it may be wise to reserve diagnosis and merely to use a descriptive, noncommittal term, such as "follicular hypertrophy," to denote the condition. Subsequent observation and biopsy frequently will bear out the suspicion that the condition in question is an early instance of follicular lymphoblastoma.

The differential criteria listed are:

HISTOLOGIC DIFFERENCES BETWEEN FOLLICULAR LYMPHOBLASTOMA AND INFLAMMATORY HYPERPLASIA

Follicular Lymphoblastoma		Simple hyperplasia of inflammatory or toxic origin	
Follicles	{	Larger and more numerous	Smaller and less numerous
		Closely packed	Scattered
		Diffuse throughout node	Arranged around cortex in concentric rows
		Frequent in medulla	Few in medulla
		Uniformly large	Vary in size
		Tend to fuse	Discrete
Interfollicular Tissue	{	Cells densely packed	Cells scattered
		Condensation of reticulum	Loose reticulum
		Sinuses narrowed or blocked	Sinuses open, often dilated
		Slight proliferation of reticular cells	Marked proliferation of reticular cells

SPUTUM, Aspiration of, From Adults, Auger, W. J. J. A. M. A. 115: 1186, 1940.

A brief study was carried out on 13 adults with pneumonia who reputedly could not cough or bring up satisfactory sputum for examination.

In all 13 cases sufficient sputum was obtainable from either the larynx or the nasopharynx by the use of the aspiration method.

No advantage was found in nasopharyngeal secretions as compared with secretions from the larynx in the typing of pneumococci in pneumonia among adults.

The laryngeal aspiration method of collecting sputum, whether obtained by syringe and finger valve or by a sputum trap and machine suction, has been suggested for adults when voluntary efforts at expectoration have failed. This method is also recommended for obtaining sputum from tuberculous patients.

It is suggested that the person who examines the sputum in the laboratory should obtain the sputum.

BRUCELLA, An Evaluation of the Opsonocytophagic Test, Wise, B. Am. J. M. Sc. 200: 520, 1940.

The usual range of the Brucella opsonocytophagic index in normal individuals, as expressed by the index number, is from 0 to 30.

A positive Brucella opsonocytophagic index is specific, that is, the individual's blood that is positive for Brucella does not phagocyte other organisms to any considerable degree.

A significant difference in the phagocytosis of nonencapsulated and encapsulated strains of Brucella organisms exists, and should be considered when this test is carried out.

The Brucella opsonocytophagic index has its greatest usefulness in indicating contact with Brucella organisms and, of the usual laboratory tests, is the single most useful test for survey work.

The Brucella opsonocytophagic index is not diagnostic of active Brucella infection and may be negative when active infection exists.

TUBERCLE BACILLI, Demonstration of, Steenken, Wm., Jr. Am. Rev. Tuberc. 42: 548, 1940.

An alcohol-precipitated protein from pleural fluid and white of egg has been recommended for sedimenting tubercle bacilli from urine and spinal fluid in place of tannic acid.

The sedimented protein is soluble in 4.0 per cent sodium hydroxide. It gives a straw color which does not interfere with color change of the indicator used for adjusting the pH.

The protein is not inhibitory to the growth of the tubercle bacillus as the tannates are.

The method follows:

Preparation of protein: All glassware used in the preparation of the protein must stand in cleaning solution (mixture of sulfuric acid and potassium dichromate) overnight.

Clear colored pleural fluid, filtered through paper and centrifuged at high speed for a half hour, was diluted with an equal volume of distilled water and passed through an "N" Berkefeld filter. This filtrate was sterilized at 60° C. for one hour, and the protein was precipitated by the addition of three volumes of 95 per cent alcohol for every volume of pleural fluid. The resulting mixture of precipitated protein and alcohol was allowed to stand in the icebox overnight, at the end of which time the alcohol was decanted and the remaining protein washed three times with equal volumes of 95 per cent alcohol. Finally it was centrifuged and the resulting sediment was suspended in 50 per cent alcohol, then it was diluted so that each cubic centimeter contained 50 mg. dry weight of the protein. It was then sterilized at 50° C. for one hour and stored in the icebox until ready for use.

The protein may also be prepared from the white of egg using the same procedure, only it is recommended that the eggs be fresh and that the whites be dissolved in an equal volume of water before precipitating with the alcohol.

Treatment of specimen: A twenty-four-hour specimen of urine is collected in the usual manner, and for every 100 c.c. of urine, 1 c.c. of the protein suspension is added. The resulting mixture of protein and urine is allowed to stand in the icebox for twenty-four

hours. At the end of this time most of the protein will have sedimented to the bottom of the bottle carrying the tubercle bacilli with it. The supernatant urine is then siphoned off and the sediment is centrifuged at high speed for ten minutes to free it of the residual urine. The sediment is taken up with an equal volume of 4 per cent sodium hydroxide and placed in the incubator for half an hour. The digested material is then centrifuged at high speed and the supernatant fluid is decanted. The sediment is neutralized to pH 7.0 with tenth-normal hydrochloric acid containing phenol red, when it is ready for smear culture or animal inoculation.

Tubercle bacilli may be recovered from spinal fluid by the addition of 0.1 c.c. of protein for every 10 c.c. of spinal fluid. The mixture is then centrifuged at high speed. The sediment is now ready for smear culture or animal inoculation.

Fluids of higher specific gravity that are miscible with water may be sedimented if diluted with sterile distilled water. Other alcohol-precipitated proteins may also act as sedimenting agents.

The criticism may arise that the pleural fluids used to prepare the protein may have been contaminated with a few tubercle bacilli, but such organisms would be dead. The necessary check of all positive urine or spinal fluid smears by culture of guinea pig inoculation would remove this objection.

COVER SLIPS, A Practical Substitute for, Norris, J. C. J. A. M. A. 115: 1099, 1940.

Norris recommends plastacele securable in sheets (C-12-7511-sheet 20 by 50 inches by the E. I. DuPont Co., 626 Schuyler Avenue, Arlington, N. J., at \$1.00 per sheet). One sheet can be cut into about 1,000 cover slips.

TUBERCULIN REACTION, The Instability of, Dahlstrom, A. W. Am. Rev. Tuberc. 42: 471, 1940.

The dispensary records of 3,919 members of 513 families under observation from five to fifteen years were examined to determine whether the tuberculin reaction, once established, remains constant, and, if not, to determine the circumstances of inconsistency, with particular reference to the original intensity of the reaction, the degree of exposure to tuberculosis, the presence of tuberculous lesions, race, age, and sex, and finally the season of the year.

Of the group examined, 2,490 were positive to tuberculin in at least one examination, and 276, or 11.1 per cent of these, passed from the positive to the negative state during the period of observation in the dispensary. The lower the original degree of sensitiveness, the greater was the likelihood of reversal from positive to negative reaction. Only 0.4 per cent of 1,090 people giving a three-plus reaction to the standard first dose of tuberculin became tuberculin-negative, whereas the negative state supervened in 70 per cent of 185 persons, giving only a one-plus reaction to the second dose.

The greater the degree of family exposure, the more likely a reaction was to remain positive. In families with no history of tuberculosis in any member, 24 per cent of the members became negative, whereas among 63 reactors in families in which a patient with positive sputum resided constantly, only one person (1.6 per cent) became negative.

The tuberculin reaction never became negative in the group under consideration in the presence of lesions of active reinfection type tuberculosis, but became negative in a small number of cases of tuberculous lesions of the type diagnosed by x-ray examination only. The list included 2 cases diagnosed as active childhood type tuberculosis, 5 cases with inactive or suspected reinfection type tuberculosis, and 11 cases with x-ray evidence of calcified childhood tuberculosis. Altogether, reactive capacity disappeared in 0.72 per cent of the total number of patients with recognizable tuberculous lesions of any sort.

No significant correlation of instability of the tuberculin reaction with sex was discovered, but there was definite correlation with age. The overwhelming majority of the unstable reactors were children. Reversion to negative reaction proved rare in adult life. Race possibly played a part, but uncontrollable variables made definite determination impossible. When comparison was made of two largest racial groups, Italians and Negroes, the former appeared to react less intensely and to have more tendency to lose a sensitivity once it was conferred.

GRANULOMA, Systemic Reticulo-endothelial, Wallgren, A. *Am. J. Dis. Child.* 60: 471, 1940.

A description is given of two clinically and anatomically investigated patients with systemic reticulo-endothelial granuloma, they being 4 months and 2½ years of age, respectively. These cases, which essentially show great similarities, occupy intermediate positions, one of them between so-called infectious reticulo-endotheliosis and Letterer-Siwe disease, and the other between the latter malady and Schüller-Christian disease.

These three types of systemic reticulo-endotheliosis, hitherto regarded as different diseases, are discussed, and reasons are advanced to show that the distinguishing features between the two first mentioned are rather arbitrary and nonessential, and that the anatomic and clinical dissimilarities that may exist between nonlipoid reticulo-endotheliosis and Schüller-Christian disease are easily explained by the difference in age of the patients, the unequally malignant or benign course, mainly due to this difference in age, and the different localization of the morbid changes. Transitional types are found between characteristic cases of Schüller-Christian disease and Letterer-Siwe disease and also between those of the latter and so-called infectious reticuloendotheliosis.

ANEMIA, "Target-Cell," Dameshek, W. *Am. J. M. Sc.* 200: 445, 1940.

In an Italian youth with hypochromic anemia, splenomegaly, and a hemolytic type of icterus, unusual changes were discovered in the red blood cells and the bones. About a third of the red blood cells presented the appearance of "targets" or "bull's eyes"; these cells were unusually resistant to hypotonic solutions of sodium chloride. No nucleated red blood cells were present. Generalized osteoporotic changes with great thickening of the skull were present; in addition, a bony tumor arising from a rib encroached on the right upper lung. Target cells have been described in sickle-cell anemia, cirrhosis of the liver, chronic hypochromic anemia after splenectomy, and in other conditions. The present studies have shown that they are also common in Cooley's erythroblastic anemia.

The condition of "target-cell anemia," as described in this paper, may be a formes frustes, an anerythroblastic type of Cooley's erythroblastic anemia or a closely related condition. The possibility is broached that Cooley's anemia, sickle-cell anemia, and target-cell anemia are related conditions with target cells and increased saline resistance as common denominators. In Cooley's anemia the target cell is probably a more fundamental abnormality than the erythroblast, and may represent the basic hereditary defect. In these atypical hemolytic states, a lack of response to splenectomy further differentiates them from most cases of congenital and acquired hemolytic icterus.

Note: This condition has also been described by Wintrobe, Mathews, Pollack, and Dobyns (*J. A. M. A.* 114: 1530, 1940).

HYPERTENSION, Orthostatic, McCann, W. S. *J. A. M. A.* 115: 573, 1940.

In some instances of nephroptosis the erect posture may result in orthostatic elevation of the blood pressure, with diminution of the total renal blood flow and with relative consistency of glomerular filtration, though the "filtration fraction" is increased. The clearance ratio of diodrast to inulin is decreased in erect posture as compared with that in recumbent posture.

Patients with normal blood pressure and those with hypertension but without nephroptosis did not exhibit these changes.

Hypertensive patients should be studied with regard to the effect of posture on the blood pressure by comparing the pressure during ordinary activity with that found after a period of strict recumbency. Those in whom a marked orthostatic effect is demonstrated should receive pyelographic study and treatment by appropriate support of the kidneys which are ptosed. Cerebral, ocular, and cardiac symptoms may be relieved by the stabilization of blood pressure which results from such measures.

TOBACCO, Cutaneous Manifestation From, Barksdale, E. E. J. A. M. A. 115: 672, 1940.

It has been proved by other workers and the author that tobacco contains arsenic. It is common knowledge to those living in a tobacco section that farmers freely use lead arsenate as an insecticide to kill the corn worm. Nothing has been done or probably can be done in either the agricultural or manufacturing process to remove it. A series of cases with exfoliative dermatitis and positive blood arsenic, whose sources of arsenic were thought to be tobacco, was observed. The blood in a series of cases of severe dermatoses and normal individuals has been analyzed for arsenic and found to be negative, even though the patients were heavy smokers. It is thought that there is a sufficient amount of arsenic in tobacco to have a very detrimental effect in cases of postarsphenamine dermatitis.

It is realized that the Gutzeit test may not be sensitive enough to determine a difference in the blood arsenic of smokers and nonsmokers.

It is believed that patients get this dermatitis because they are hypersensitive or allergic to arsenic.

This paper has attempted to present a theory. Its ultimate proof depends on the collaboration of other workers.

SULFAPYRIDINE, Pathologic Changes Following Prolonged Administration of Sulfathiazole and, Rake, G., van Dyke, H. B., and Corwin, W. C. Am. J. M. Sc. 200: 353, 1940.

Sulfathiazole when given as 2 per cent of the diet killed 77 per cent of mice during a four-week period and produced lesions chiefly in the spleen and genitourinary tract. Sulfapyridine was not lethal and produced fewer pathologic changes.

In rats sulfapyridine was twice as toxic as sulfathiazole as shown both by the effect on the growth curve and by the lesions produced in the genitourinary tract.

In monkeys receiving a single daily dose sulfapyridine was more toxic than sulfathiazole, as shown by the lesions in the genitourinary tract and, to a lesser extent, by loss of weight and leucopenia.

LEUKOCYTES, Motility and Chemotaxis of, in Health and Disease, Mallery, O. T., Jr., and McCutcheon, M. Am. J. M. Sc. 200: 394, 1940.

The activity of polymorphonuclear leucocytes from a series of patients acutely ill, most of them with infections, was compared in vitro with that of the observer's leucocytes and of leucocytes from patients not acutely ill. Decreased rate of locomotion and less direct approach to bacteria were shown by leucocytes of the acutely ill persons. In leucocytes of some patients who were gravely ill decline in motility and chemotactic response was progressive, whereas the observer's leucocytes maintained their activity unimpaired for hours. The functional changes observed would tend toward lowering resistance to infection. These experiments emphasize the fact that in severe illness the function not merely of whole organs but of individual cells is depressed, and they afford a method for quantitative measurement of changes in cellular function.

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, 201 West Franklin Street, Richmond, Va.

WELL written, easy to read, this book is short, concise, and well translated. The author takes up the various anorectal conditions one by one, discussing the etiology, pathology, and treatment of each. The sections on etiology present a new concept which is of interest. It is brought out that the underlying cause of hemorrhoids, anal fissure, fistula in ano, pruritus ani, and rectal prolapse is a congestion of the portal circulation. The author maintains that all are merely symptoms of the same condition. He further points out that all respond to the treatment, namely, injection of a sclerosing solution around the hemorrhoidal veins. A chapter is included on the instruments necessary for injection treatment.

The book contains many well-reproduced color photographs and drawings in addition to clear-cut black and white illustrations.

ALTHOUGH the first edition of this volume appeared as recently as 1936, it has been necessary to put out a new edition every two years, this being the third. This volume has several unusual features. It contains practically fifteen hundred pages. It is more abundantly illustrated than any other textbook on the practice of medicine, there being 562 illustrations, 48 of them in color. This is the first medical text using the new green tinted paper which reduces glare and eyestrain. The discussion of individual diseases is broader than in other similar texts in that discussion includes illustrations which are usually found in texts on physical diagnosis and clinical pathology. In other words, the discussion is broader. At the same time there is no superfluous verbiage, the textual presentation being very succinct. This volume may be highly recommended.

SINCE short wave therapy is based on physical, technical, and medical principles, it is fortunate that collaboration of a physicist and a physician led to the production of this book. A short introduction to the physical theory of oscillations is given, followed by the most important methods of measurement for technicians and doctors. Important considerations about the choice of apparatus are mentioned. The medical section contains a review of the

 ‡Foundations of Short Wave Therapy. Physics—Technics—Indications. An Introduction to the Physico-Technical Principles and Medical Applications of Short Electric Waves for Physicians and Biologists. Physics and Technics. By Wolfgang Holzer, Dr. Ing., Assistant in the Physiological Institute of the University of Vienna. Medical Applications. By Eugen Weissenberg, Dr. Med., Medical Superintendent of the Short Wave Section of the University Clinic for Nervous and Mental Diseases in Vienna. Translated by Justina Wilson, F.R.C.P. Edin., D.M.R.E. Cantab., and Charles M. Dowse, B.Sc. Eng. Lond., A.M.I.E.E. Cloth, 228 pages, with 53 illustrations and 10 tables, \$5.00. Distributed by Chemical Publishing Company, Inc., 148 Lafayette St., New York.

whole field of indications for short waves. Diseases of the skin, such as varicose eczema and localized suppurating inflammations, inflammations of the soft tissues, and diseases of bones and joints are particularly amenable to short wave therapy. It is remarked that gonococcal arthritis reacts especially well. Diseases of the lungs, including asthma, are also said to respond. It would appear that there is no diseased organ system that cannot be benefited to a greater or lesser extent by this technique. The book is ably translated and contains a very complete bibliography. It is felt that this is an excellent presentation and will be of equal value to clinicians and experimental workers.

Clinical Parasitology*

THE second edition of this book is most complete and extremely well illustrated.

While older books on human parasitology have classified parasites on the basis of their location or the manner of their activity in the human body, the classification in this volume is in accordance with the international code of zoological nomenclature. This same trend toward more scientific classification is seen in bacteriology, mycology, and allergy. It represents a natural scientific evolution and facilitates precision in discussion.

The volume goes farther than the older writings on human parasites, including not only protozoa and helminths, but also the arthropods, spiders, lice, bees, flies, fleas, and similar animal parasites or enemies.

A technical appendix provides ample instruction for laboratory study.

Histological Technic†

AS STATED by the author in his preface, the major purpose of this work is to present modifications of methods of tissue fixation, section-making, and staining which in his experience make the results more quickly available to the pathologist. Consistent with this aim, Krajian not only presents the generally accepted methods but also seventeen of his own modifications.

The book is well illustrated, reasonably small, and easy on the eyes because of the new type paper with a slightly greenish tint that reduces glare. It should become a useful and valuable laboratory handbook.

Bacillary and Rickettsial Infections. Acute and Chronic‡

THIS volume has a really new approach. Although history, epidemiology, prevention, symptomatology, diagnosis, and treatment are included under the various diseases, the history of the development of our present understanding is given major prominence. The volume is one which may be read for pleasure when one is relaxed and desires to broaden the horizon of his understanding of the problems of medicine as they have been solved throughout the centuries.

Marginal notations appearing as inserts are abundant and facilitate immediate orientation for those who may wish to refer to some specific phases of the discussion.

As indicated in the title, the coverage is of bacillary and rickettsial diseases, and does not include virus diseases or other forms of bacterial infection.

The Macmillan Company, New York, 1940.

The Biological Reaction*

THE reader will be astonished to find that despite this general title the authors are only discussing tuberculosis. Of course, they approach their subject from a general point of view. It is obvious that for them tuberculosis, as the disease with which they both are most familiar, serves only as an example to demonstrate how the complexity of the various factors involved in the biological reaction of the organism against a disease can be analyzed. The results of their analysis of the reaction of tuberculosis patients and animals, if correctly interpreted, are highly important for the treatment and prophylaxis of this disease. In the first part of the book, Hofflin (Victoria, Canada) gives the theoretical arguments and the mathematical proofs for their method of expressing the "biological reaction" in figures. A series of six to ten differential leucocyte counts (classification of Schilling) are made at intervals of two hours in order to interpret the oscillation of the biological reaction. The minimal and maximal differences of the various counts with one another, and the deviations of their average values from the standard values are the basis for the calculation of figures expressing seven variables of the biological reaction: extensity of foci, intensity of foci, allergy, general resistance, specific resistance, index of immunity, and metabolic index. These figures are then analyzed by means of a Fournier series and their correlations are represented geometrically in graphs with logarithmic scales (secondary analysis). To complete the functional analysis, two series of differential counts are made on two consecutive days, one before, the second after, an intracutaneous tuberculin injection. Both their graphical representations are compared and interpreted concerning their relative position to one another according to Hofflin's experience with cattle tuberculosis. In the second part of the book, Bueher (Zürich, Switzerland) reports the clinical proofs and the practical application of the new method for the diagnosis and prognosis of human tuberculosis. The third part of the book is entitled "Quantum Diagnostic. Foundations of a Modern Tuberculosis Therapy and Prophylaxis. Practical and Theoretical Conclusions." An "active" gold preparation (erysatox, described as a gold-sodium-sulfur combination) combined with a "biological carrier" (ompotan, the chemical nature of which the authors do not even intimate) is given intravenously or orally. Not only good clinical results are reported, but the new diagnostic method of the authors gives the possibility of finding out the favorable moment at which the therapy has to start, and of demonstrating later on the improvement in the biological reaction of the patients. While this therapy is declared to be a specific one, the prophylaxis proposed and tried with success by the authors on animals and patients has as its aim to raise the non-specific immunity without producing allergic reactions as proved by their new "quantum diagnostic." The prophylaxis consists in feeding a complex emulsion of large molecular lipoids, proteins, and polysaccharides, of which no further descriptions are given.

Without doubt the authors discuss many very interesting and important observations. However, only few readers will be able to follow their train of thoughts and understand and accept their conclusions. Unfortunately, the mathematical part is kept so brief that it will be difficult for the average physician to understand it, and especially to realize why one has to assume that the various proposed formulas can express allergy, immunity, resistance, etc. The experimental and clinical evidences offered are not convincing enough to vindicate such comprehensive theories.

—Ernst Fischer, M.D.

PROGRESS

SOME RECENT ADVANCES IN DERMATOLOGIC THERAPY

MAISON B. SULZBERGER, M.D., AND ELLIS P. COPE, M.D., NEW YORK, N. Y.

THE material for the present summary has been gathered from the literature of the last two years. Selection has been entirely arbitrary, and many contributions of undoubted value have had to be omitted. Reference is made to some purely experimental work, not because it represents a practical advance in present dermatology, but because it may be the source of future progress in therapy.

VITAMIN THERAPY

The dermatologist deals primarily with the skin, the largest and most accessible organ of the human body. No other single organ offers such scope for the study of morphology and function in both health and disease. No other organ is subject to external assault by physical, chemical, mechanical, and biological agents; and at the same time, to internal onslaught by almost all the factors causing disease in more sheltered tissues. The dermatologist must, therefore, be an alert "internist" as well as a competent "externist." In many so-called "systemic diseases" a careful study of the skin and orificial mucous membranes will offer either supportive or conclusive diagnostic evidence (criteria). The avitaminoses (or "dysvitaminoses" as we prefer to call them) are a characteristic group in this category. However, the significance of the dermatologic approach to the study and management of vitamin deficiency is twofold. In the first place, it embraces the recognition of the classic general as well as local cutaneous manifestations of the various deficiency syndromes; in the second place, it includes the administration of vitamins to produce therapeutic effects on cutaneous lesions, as well as in order to achieve systemic effects or to build general resistance.

It is our opinion that many cases of vitamin "deficiencies" are not true deficiencies, but rather abnormal conditions of demand, utilization, and transport of the respective vitamins, "dysvitaminoses" (Sulzberger¹). Moreover,

in numerous instances, it seems as though improvement takes place faster if several, and not only one, of the vitamins are administered. However, it is, of course, usually necessary to give that particular vitamin or complex which is most obviously needed in dosage much higher than that of the other vitamins.

Goodman, Kanof, Bacr, and one of us (M. B. S.)² have shown that some cases of keratosis pilaris, formes trustes of ichthyosis, lichen spinulosus with or without cicatrizing alopecia, and brittleness of the nails are benefitted by large doses of *vitamin A*.

Probably the most striking of the newer studies on the role of vitamin A in dermatology is contained in the observations of Peck, Chargin, and Sobotka³ on keratosis follicularis (Darier's disease). These investigators found that individuals with Darier's disease had a normal or increased amount of the provitamin A (carotene) in their blood serum, but a decidedly lower than normal ratio of vitamin A itself. These determinations were made by use of the photometer,⁴ with which quantitative estimations of vitamin A in blood serum are made according to the method of Carr and Price.⁴ The estimations were confirmed by the dark adaptation method of Hecht and Mandelbaum.⁵ It was further found that the dyskeratosis gradually subsided when serum vitamin A levels were raised to normal by the administration of large amounts (200,000 I.U. daily) of vitamin A concentrate, and recurred when this treatment was stopped or the dosage reduced. On the basis of this preliminary work, Peck and his collaborators believe Darier's disease to be due to an hereditary physiologic weakness in the absorption of vitamin A or in its conversion from the provitamin.

Recently, also, the dermatologic condition known as pityriasis rubra pilaris has been successfully treated by vitamin A in large doses. Brunsting and Sheard⁶ had previously found that dark adaptation tests were similar to those later reported by Peck and co-workers in Darier's disease, and improvement in the dark adaptation which followed vitamin A therapy was, to some degree, paralleled by clinical improvement in the dermatosis. In this report, attention is drawn to the impairment of dark adaptation sometimes found associated with cirrhosis of the liver.⁷ Recently, cases have been reported of the beneficial effect of vitamin B complex on pityriasis rubra pilaris.⁸ This observation may lead to the assumption that the vitamin B complex produces an improvement in liver function which in turn permits the proper utilization of vitamin A, or the conversion of provitamin A to vitamin A. The reviewers have used vitamin A with some success in cases of phrynoderma, in individuals with hypothyroid habitus, and in various forms of "dryness of the skin," of lichen pilaris, of mild ichthyosis, and of follicular keratoses; and in patients giving a history of long-continued ingestion of mineral oil or of prolonged indulgence in some dietary fad. Debilitated or elderly patients with chronic dyskeratotic disease, or those suffering with chronic ulcers often respond to large doses of vitamin A, preferably complemented by B complex.

The *vitamin B complex* is justly receiving a lion's share of attention at present. It is our belief that, with a few notable exceptions, such as pellagra and polyneuritis, the vitamin B complex components are most effectively admin-

*Manufactured by the Central Scientific Co., Chicago, Ill.

istered as injections of whole crude liver extract (not the refined or concentrated preparations). This form is cheaper and much more efficacious than the 2 to 15 units per cubic centimeter products often employed. In many cases liver injections seem to be more effective also than much higher dosage of the present known vitamin B factors given by mouth. This may be due (1) to an unknown factor present in the crude liver; or (2) to a synergistic action of the various fractions of liver when given parenterally; or (3) to an alteration in composition of the concentrated or crystalline products produced by pharmaceutical houses for oral administration; or (4) to a faulty or selective alimentary absorption of the oral medication.

Madden⁹ reports vitamin B₁ to be a valuable adjunct in the therapy of psoriasis. There is a growing literature on vitamin B₁ therapy in pink disease (acrodynia) in children.¹⁰ Its use is well known in beriberi, and in the peripheral neuropathies of pellagra, alcoholism, and pregnancy.

Riboflavin (vitamin B₂) deficiency is characterized by some combination of the following signs and symptoms: redness of the buccal surface of the lips and abnormal redness of the vermilion borders with desquamation. There is usually maceration and fissuring, and sometimes rhagades-like lesions at the commissures. Seborrhea of the naso-labial folds, alae nasi, eyelids, and ears is frequent. There may be a specific type of glossitis with a purple-red color, fissuring, and coarse granular appearance. Conjunctival, scleral, and corneal injection and vascularization may be seen. The patient complains of burning of the eyeballs, roughening of the lids, visual fatigue, and photophobia.¹¹ All these conditions are promptly remedied by specific treatment—except the visual disturbances in long-standing cases. In dermatologic practice two points are worthy of stress in connection with the recent literature on riboflavin: the first is that *ordinary perlèche*, as occurring in children, or after trauma (dentist) and as seen so commonly by skin specialists, is *not a riboflavin deficiency and does not respond to riboflavin therapy*. The second point to be made is that while many of the corneal ulcers of *rosacea keratitis* respond to vitamin B₂, the cutaneous acne and *rosacea* remain unaffected, and do not, as a rule, respond to riboflavin.

Smith, Smith, and Callaway¹² describe a skin condition in pellagrins which they term "dyssebacia." The lesions, chiefly on the face, are characterized by dryness of the skin and the presence of plugs of inspissated sebum projecting from the sebaceous follicles. Dyssebacia is readily cured by autoclaved yeast by mouth or crude liver extract by injection, but is uninfluenced by oral administration of vitamin B₁ and liver extract. Nicotinic acid is effective but requires a much longer time than yeast or crude extract of liver.

The role of *nicotinic acid* in pellagra therapy is well known, as are its supposed and reported effects in alleviating some of the disagreeable subjective effects in sulfonamide therapy. The reviewers believe it may exert some beneficial effect in some cases of lupus erythematosus, perhaps by reducing the photosensitivity in this disease. They believe also that some patients tolerate oral bismuth (sobilminol) better while taking nicotinic acid, having less tendency to stomatitis and fewer gastric upsets. King¹³ reports the disappearance of organisms of Vincent's angina in forty-eight to seventy-two hours with nicotinic acid therapy.

Vincent's angina and stomatitis are important, and are at present causing *much disability in military concentrations and defense projects*, and King's findings should merit further study.

The status of *pantothenic acid, biotin (vitamin H)*, and other factors of the vitamin B complex has not been settled. A very thought-stimulating paper by György¹⁴ discusses the possible relationship of these factors (as well as thiamine and riboflavin) to the sealy desquamative dermatoses in man. He has experimentally produced and cured in animals conditions similar to those of the "seborrheic diathesis" in man.

Spies¹⁵ points out that pantothenic acid and riboflavin are mutually complementary, and believes the former to be a dietary necessity.

Kristensen and Vendel¹⁶ claim to have effected a prompt, universal, and permanent clearing in 13 acute and 7 chronic cases of eczema treated with the vitamin B complex.

The Plummer-Vinson syndrome, characterized by anemia, dysphagia, glossitis, cheilitis, and spoon nails, is considered a precancerosis, probably related to vitamin B complex deficiency.¹⁷ Notable among other suggested uses of vitamin B complex are its use in the treatment of (1) glossitis and stomatitis accompanying sprue, pernicious anemia, and pellagra;¹⁷ (2) certain cases of neurodermatitis of the back and sides of neck and the elbow flexures;¹⁷ (3) certain cases of moniliasis;¹⁷ (4) cases of lupus erythematosus with extreme sensitivity to light;¹⁷ (5) some cases of kraurosis vulvae.¹⁷

Gross¹⁸ reports improvement in cases of kraurosis vulvae by combined administration of vitamin A, riboflavin, and liver extract. He stresses the interrelationship between hormone and vitamin therapy because some of these cases may respond to either type of treatment. He believes some of the very apparent increased effectiveness of crude liver extract may be due to biotin, although it is supposed to be left in the residue of extraction. Two other important observations are made by Gross: (1) pantothenic acid therapy response depends on much larger dosage than is found in vitamin B complex; and (2) very large dosage of thiamine chloride may cause a relative deficiency of nicotinic acid due to increased requirement, although there is no known toxicity to vitamin B complex even in huge doses.

One of us (M. B. S.), in discussing vitamins A and C,¹ mentions certain instances of quicker improvement in phrynodema (dry skins and follicular keratoses) being effected by *vitamin C* therapy than by administration of vitamin A. He also describes Sjögren's¹⁹ syndrome, which is very similar to the Plummer-Vinson disease in all its manifestations. He states that this condition, which is usually seen in women at the climacteric, is uninfluenced by iron or vitamin B complex, but is much improved by large doses of vitamin A. He also makes a point of the possible relationship between malignant epithelial changes and dysvitaminosis A.

The dermatologic aspects of vitamin C are discussed by Saunders,²⁰ who states that it exerts a regulatory action on pigment production in scurvy and in Addison's disease, and favorably influences chloasma uterinum. Subclinical scurvy is important in dermatologic diagnosis and management because it is

more common than is usually supposed; and because it may intensify the hemorrhagic tendency of any existing eruption.¹⁷

Scarborough²¹ believes the hemorrhage of vitamin C deficiency to be ecchymotic or deep in muscles and tissues in contrast to that of vitamin P deficiency, which is petechial and circumpilar. Gorrie²² has successfully treated purpura hemorrhagica following neoarsphenamine with vitamin P (hesperidin). Three cases of Henoch-Schönlein type, one of rheumatic and one of symptomatic purpura, were "cured" by Hiramatsu²³ with hesperidin. He believes, however, the effects of vitamin P therapy are enhanced by vitamin C.

At one time or another vitamin D has been reported as useful, if not specific, in almost every chronic dermatologic condition. Wise and one of us (M. B. S.) have stated that their experience with vitamin D has been disappointing in the major uses for which it has been recommended in dermatology; namely, psoriasis, acne vulgaris, and pemphigus.²⁴

The beneficial effect of vitamin E (α -tocopherol) on amyotrophic lateral sclerosis, reported by Wechsler, led Baer²⁵ to treat a case of *dermatomyositis* with this drug. The patient improved under this therapy, suffered a remission when treatment was stopped, and continued to improve with resumption of α -tocopherol intramuscularly.

The role of the *unsaturated fatty acids* as vitamins is not clear. It is known that certain of these acids, such as linolenic acid, will cure rat "acrodynia" produced by pyridoxine deficiency.¹⁴ Linolenic acid also exerts a vitamin A-like effect on nail nutrition,²⁷ although its isomer, α -eleostearic acid, is without effect.

Gross²⁸ has shown that animals fed vitamin B₆, together with curative doses of essential fatty acids, were entirely protected against vitamin B₆ deficiency, but slowly developed the skin lesions of the *filtrate-factor* deficiency and died from the lack of these factors.

SULFONAMIDES IN DERMATOLOGY

The history of the sulfonamides in dermatology is much like that of their use in general medicine. The statement is almost warranted that sulfonamides have been tried on every dermatologic entity except the frank malignancies, nevi, and atrophies. As in other fields of medicine, sulfonamide therapy may be said in many respects to be still in the experimental stages. There are, of course, certain well-recognized dermatologic indications where one of the sulfonamides may be the therapy of choice, others where there is enough established evidence of possible benefit to justify its use, and then the vast limbo of "shooting arrows in the air" and of the "last resort" cases.

It is certainly not within the scope of this paper to discuss the mode of action of the sulfonamides, but the opinion may be ventured that it is probably an effect on the oxygen metabolism of the germ itself. The reader may be referred to authoritative papers on this subject.^{29, 30} The selection of the drug itself offers somewhat of a problem, some authors reporting better results in general with *sulfapyridine* than with *sulfanilamide*.

Sulfathiazole is generally accepted as being the agent of choice in staphylococcal infections and is the drug most used in topical application, either as

powder or as the soluble sodium salt. In our own investigations we have found that sodium sulfathiazole is not a primary irritant to the skin, despite the high alkalinity (pH. 11:0). As a preliminary precaution patch tests were applied on 35 normal skins before we used sodium sulfathiazole therapeutically as wet compresses and irrigations. We have used this salt in 5 per cent concentrations in ointments, in emulsions, and as compresses, employing it in infected hemostatic (varicose) ulcers, in impetigo, in furuncles, and in carbuncles. In the latter we have used a complementary oral dosage of 4.0 to 7.0 Gm. daily, trying to maintain a blood level in excess of 2.5 mg. per cent. We can recommend this combination of topical and internal therapy for certain severe pyodermas that do not respond to the usual older measures.

In agreement with observers in other fields of medicine, we have found that, in general, it may be stated that the more acute the dermatosis, the better the results with sulfonamide therapy. Either *sulfanilamide* or *sulfapyridine* has been reported to be definitely useful in the following dermatologic conditions, among others: (1) streptococcic cellulitis and lymphangitis; (2) streptococcic ulcers; (3) erysipelas; (4) erythema multiforme (some types); (5) chancreoid; (6) lymphogranuloma venereum; (7) subacute discoid type of lupus erythematosus. There have been many interesting reports of further uses of sulfonamides in isolated cases or in too short a series to be conclusive evidence for general acceptance. Anderson³¹ and Abramowitz³² report cures of patients with acute disseminated lupus erythematosus. Glyn-Hughes and Spence³³ report a series of 12 patients with lupus erythematosus in whom all gave favorable responses and six were cured with sulfapyridine. On the other hand, Wile and Holman³⁴ report discouraging results with sulfonamides in acute disseminated lupus erythematosus.

Dobson³⁵ believes sulfanilamide a valuable adjunct in the treatment of actinomyces. Sehoeh and Shelmire³⁶ report success with sulfanilamide in the treatment of erysipeloid of Rosenbach.

Good initial results in dermatitis herpetiformis and sycosis vulgaris have seldom been maintained.

It is almost an impertinence here to discuss the general systemic signs and symptoms of the toxicity of the sulfonamides, since they have been so widely described and so accurately detailed. The cutaneous reactions usually seen are the well-known morbilliform eruptions and the less known dermatitis from photosensitivity, *erythema multiforme-like* and *erythema nodosum-like* dermatoses, scarlatiniform eruptions, fixed eruptions, stomatitis, urticaria, purpura, varioliform eruptions, and exfoliative dermatitis.³⁷ Sulfathiazole in many instances presents a conjunctivitis or "pink eye" which may be the initial—or even the only—manifestation of intolerance. Baer states he has observed generalization in two patients with psoriasis following a sulfonamide eruption.³⁸ He believes this to be due to a Koebner phenomenon at the site of local injury due to the eruption. This observation is well to keep in mind with reference to other photosensitizing agents that may be ingested by psoriatics undergoing ultraviolet light treatments.

HORMONAL THERAPY (ENDOCRINOLOGIC THERAPY)

The present enthusiasm for endocrine therapy is on a par with that for the sulfonamides and vitamins. Many liters of *estrogenic substances* and of *anterior-pituitary-like substances* are being administered to women presenting various dermatoses at the menopause. However, specific treatment with *estrogens* in dermatology is almost limited to *senile pruritus* and *kraurosis in the female*. As early as 1935 Davis³⁹ reported good results with suppositories of 75 R.U. of amniotin (Squibb) in kraurosis. Recently stilbesterol has been reported to be highly effective when given by mouth in doses ranging from 0.1 to 10 mg. daily; or, topically, in ointments containing 10 to 20 mg. per ounce.⁴⁰ (In the way of non-endocrinologic treatment Saville⁴¹ claims excellent results in both simple leucoplakia and kraurosis with diathermy, using a belt about the hips or a pubic plate and an all-metal electrode high in the vagina. Relief is obtained in four to fifteen treatments, using the factors fifteen minutes and 0.7 to 1.5 amperes.) Lane⁴² reports the clearing of an *oral leucoplakia* in two patients by use of estradiol.

Folliculin has been advised in *alopecia* for both men and women. *Testosterone* is known to grow hair, sometimes on face and chest, to the embarrassment of young women. We have recently seen several cases of young women treated with testosterone for menorrhagia who presented new growth of hair on face and body, deepening of voice, and a deep pustular acneform eruption, most marked on borders of the face. Moreover, in patients with a tendency to acne, or even in those with only mild seborrheic habitus, many of the androgenic hormones will quite regularly produce acne. The same remark applies to eunuchs or eunuchoid persons receiving androgens.⁴³ Many of the androgen acnes we have observed have cleared up promptly upon withdrawal of the hormonal therapy (in a few days to weeks). However, a few cases have persisted for many months despite the stopping of the hormonal administration and the usual anti-acne therapy.

Feldman⁴⁴ states that six patients with generalized senile pruritus were cured by injections of 5 to 15 mg. testosterone propionate weekly. There are as yet no reports by others to confirm this interesting and important observation.

Brittleness and friability of nails can occasionally be benefited by *thyroid* therapy. Subclinical thyroid hypoaetivity may be manifested by no other clinical signs than mild dryness of the skin and hair, or brittleness of the nails. In our experience a fair number of patients with *acne vulgaris* or with *atopic dermatitis* will respond favorably to thyroid medication even though the basal metabolic rate is within the so-called normal limits.

ANTISYPHILITIC THERAPY

In our opinion the outstanding advance in antisyphilitic treatment is the massive arsenotherapy in early syphilis by some of the newer methods, including the continuous intravenous drip method.⁴⁵ The idea of Sterilisatio Magna began with Ehrlich, and was carried on in the experiments of Linser⁴⁶ and Pollitzer.⁴⁷ A modern study, begun by Chargin, Leifer, and Hyman in 1932,⁴⁸ is a masterpiece of painstaking basic preliminary work and careful clinical and laboratory observation during the treatment. The conservative conclusions

expressed by the whole group at this time are characteristic of the truly scientific attitude of the workers. The original article⁴⁵ is on the "must list" for anyone even remotely interested in syphilis or serology. Much of the data concerning serologic comparisons and interpretations has not as yet been published, and will, undoubtedly, of itself be an important contribution. It is impossible to summarize this work since the original report is, indeed, a summary. Certain conclusions regarding the possible advantages of the massive intracutaneous drip method may, however, be safely stated: (1) More patients who began treatment are cured than with the intermittent treatment (during which so many patients disappear as soon as rendered asymptomatic, only to develop later the well-known serious aftermaths of insufficient therapy). (2) The method, when mapharsen is employed, is as safe, or *almost* as safe, as the intermittent treatment in early syphilis. (3) Nitritoid reactions have been almost proved to be a "speed shock" phenomenon and are not seen in this procedure. (4) Mapharsen, as previously believed, has proved efficacious and less toxic than neoarsphenamine. (5) No major dermatitides were seen with mapharsen. (6) Serious manifestations of toxicity occur with neoarsphenamine—hemorrhagic encephalitis, peripheral neuritis, hepatitis. (7) Relapses do occur. (8) The late results, including both those due to the syphilis itself and to massive dose arsenic therapy, are not yet known. (9) It is, as yet, only an experiment, but nevertheless, an intensely interesting and valuable one.

However, as one of us (M. B. S.) has previously stated: "It is, for example, not yet known whether mapharsen could not be given several times daily by means of small syringes with effects equivalent to those obtained when the same dose is given by continuous drip."⁴⁶ At present it appears to us probable that the results obtained with mapharsen in the intravenous drip may be due not so much to the beneficial effects of the *slow drip method*, as to a *previously unrecognized lack of toxicity or broad therapeutic index of mapharsen itself in man*. If this theory proves true, one should be able to give daily large doses of mapharsen in ambulatory patients, with small syringes and without the difficulties and expense of hospitalization and drip administration.

Very recent studies, particularly those of Sehoeh and Alexander,⁵⁰ and collaborators, support the statement just quoted from the Year Book and our present opinion. For these investigators have now treated over 40 patients with early syphilis with *daily doses of 0.12 Gm. of mapharsen*. Each dose was given rapidly in 10 c.c. of water with a small syringe. The patients all were ambulatory, all continued with their occupations; none experienced the slightest untoward effects or untoward reactions. In this as yet small series the results are most promising. The disappearance of the syphilitic manifestations and the reversal of the serologic reactions were fully as good as with the drip method.

A further advance in antisyphilitic therapy is the introduction of the drug *sobisminol*,⁵¹ which can be given orally (as well as by injection) and orally compares favorably in its action with injectable bismuth preparations. However, the bismuth in this form of medication is eliminated rapidly. No depot or constant source of absorption is established with sobisminol,⁵² and *clinical relapse* has been reported on its substitution for injectable bismuth. In one

report it has seemed to have an especially beneficial influence in patients with late neurosyphilis of the tabetic type.⁵³ This benefit apparently regresses with cessation of treatment, but the drug can be given for months without signs of cumulative effects. This does not mean that it is without either major or minor toxic effects of bismuth. In our hands it has been used with gratifying results in two patients with lupus erythematosus, and in one patient with lichen planus. Other authors have reported similar good results.

The discovery by Cole, De Ore, Driver, Johnson, and Schwartz⁵⁴ represents not only a great therapeutic advance but a singularly fascinating subject for further theoretical and practical studies. These observers found that certain bismuth salts, particularly *thiobismol*, control the bouts of therapeutic malaria in the most effective manner. By controlled administration the patient can be kept free of fever and paroxysms whenever desired, and by stopping the drug the paroxysms can be allowed to recur whenever indicated. In other words, the bismuth salt keeps the patient free of malarial attacks but does not destroy the infesting plasmodia, or at least not to such a degree as to eliminate the disease; so that, after the desired interruption, the malarial treatment can be resumed without the necessity of a reinoculation. The theoretic interest as well as the practical advantages of this discovery are both great and obvious.

Saenz, Triana, and Armenteros⁵⁵ have discovered in *pinta* patients a *spirochete* morphologically identical to the *S. pallida* and *S. pertenuis*. This disease has long been known to possess most of the serologic characteristics of syphilis and the discovery reawakens or intensifies the interest in the study of cross immunity between syphilis, frambesia, and *pinta*. It is the ambition of every dermatosyphilologist to find an innocuous disease which will give a cross immunity to syphilis, paralleling that achieved in smallpox with cowpox virus (vaccine). However, little is as yet known about the immunologic relationships or the effects of extracts of microorganisms and of attenuation procedures in various human spirochetoses.

A promising aid in antisyphilitic therapy is embodied in the report by MacKee and Astrachan⁵⁶ of the mitigating influence of whole crude liver extract on the erythrodermas incident to antisyphilitic treatment. It was even found that certain individuals could continue receiving cautiously administered arsenical treatment after a major arsenical dermatitis if crude liver extract were given intramuscularly. This report represents a confirmation of, and an addition to, the findings of Genner⁵⁷ and others.

We believe the combination of a titered Kolmer, Wassermann, and Kline diagnostic and exclusion tests are sufficient, in almost every instance, for serologic diagnostic purposes and for evaluation of treatment results. The Laughlen test, with the three-minute serum inactivation modification,⁵⁸ may be valuable for pretransfusion tests.*

MISCELLANEOUS THERAPY AND PROPHYLAXIS

The recent work on *poison ivy* dermatitis assumes tremendous added importance when considered in connection with the defense program. A majority of

*The use of antigen prepared from spirochetes, as developed by Gaechtgen and reported by Erickson and Eagle (Abstract, Year Book of Dermat. and Syph., p. 733, 1941) may prove a decided advance in diagnostic serologic tests for syphilis.

the military trainees are likely to be "ivy sensitive," and to be exposed this summer. Shelmire⁵⁹ has found that the dermatitis-producing excitant is not an oil, but a dialyzable fraction of the oleoresin, soluble in water and in urine. He also reports that the excitant is not carried in smoke, as previously believed. A large and comprehensive study of *oral desensitization* is now being carried out on a nationwide scale, due to Shelmire's experiments in oral prophylaxis, which represent an extension and modification of the older work of Jay Schamberg, Strickler, and others.

Schwartz and Warren⁶⁰ have developed and advocated the use of a *sodium perborate-containing cream* for the prevention of poison ivy dermatitis. While these authors submit observations supporting the efficacy of the cream, Shelmire, on the other hand, presents experiments tending to show its lack of effective protection.⁶¹ The value of this cream is, therefore, still awaiting the final judgment of practical results on large series of exposed persons.

The treatment of *chronic ulcers* with *zinc peroxide paste* or *mass* is a valuable and relatively recent therapeutic measure. Rigid attention to selection of the powder—since not all zinc peroxide is active—preparation of the "mass" and of its application must all be observed. An excellent presentation of the rationale and technique is found in the paper of Meleney and Harvey.⁶²

We have found application of the *Aloe vera* leaf⁶³ *alva gel*,⁶⁴ and cod allantoin ointment effective in some chronic ulcers, especially the use of the leaf in some of the ulcers following radiodermatitis.

Pliofilm mitts and sheets are useful in retaining wet dressings of all types.⁶⁵

The development of a refined test material (*Lygranum*) for the diagnosis of *lymphogranuloma venereum* (*lymphopathica venerea*) by the method of Rake, McKee, and Shaffer,⁶⁶ promises to be a notable advance. In this procedure the yolk sac of the chick embryo is inoculated, and a practically pure and highly concentrated test material is obtained. We suggest that the Frei test, with original human material, and tests with this new material, be performed in parallel and in a comparative manner in a large series of cases of (1) acute and chronic, suppurative and nonsuppurative inguinal adenitis; (2) acute and chronic proctitis; (3) fistulas of rectum and genitals; (4) acute and chronic ulceration of the genitals; (5) localized elephantiasis.

Semon and Hermann⁶⁷ report improvement in *acne vulgaris* in both men and women following the administration of either protamine zinc or ordinary *insulin*. Dosage was usually 5 to 15 U. three times weekly, given without any adjuvant treatment. Exacerbations occurred upon cessation of treatment and improvement began within forty-eight hours of its resumption. The insulin therapy sprang from observations of the lag in sugar tolerance curves in acne patients. The authors state it is impossible, at the present time, to "differentiate between metabolic vagaries and disturbance of hormonal balance."

A recent innovation in the treatment of *intractable pruritus* is the *tattooing* of the anal area with red sulfide of mercury (Hollander, E.^{68a} and Turrell, R.^{68b}). Good results are reported in the majority of cases.

The use of trichophytin in erysipelas-like infections associated with dermatophytosis of the feet, as advocated by Sulzberger, Rostenberg, Jr., and

Goetze,⁶⁹ is worth trying. Individuals in whom a favorable response is expected are those showing an *immediate wheal reaction* to intracutaneous test. The dose is 0.1 c.c. of the usual 1:30 dilution given intracutaneously at five- to seven-day intervals.

The work of Becker⁷⁰ and others with *lipocaic* (Dragstet and co-workers), although apparently productive of no lasting results in *psoriasis*, is extremely interesting. The substance is a neutral, insulin-free and fat-free alcoholic extract of pancreas which apparently has selective power of converting some fats to glucose.

Conrad, Conrad, Mapother, and Weiss⁷¹ report the use of bismarsen as a valuable addition to the therapy of *lichen planus*; 0.1 Gm. given intramuscularly twice weekly exerted a favorable influence on the ordinarily refractory lesions of the mouth, of the penis, and of the hypertrophic type. Vitamin C should be administered while the bismarsen is being given.

In closing, it may be appropriate to give some direct advice from Becker:⁷² "Therapy consists, first of all, in removing precipitating factors, social and environmental; secondly, in relieving the underlying instability and exhaustion; and thirdly, in application of orthodox measures."
